Abstract

Under social-genetic assortative mating (SGAM), socio-economic status (SES) and genetically inherited traits are both assets in marriage markets, become associated in spouse pairs, and are passed together to future generations. This gives a new explanation for persistent intergenerational inequality and “genes-SES gradients” – observed genetic differences between high- and low-SES people. We model SGAM and test for it in two large surveys from Great Britain and Norway. Spouses of earlier-born siblings have genetics predicting more education. This effect is mediated by individuals’ own education and income. Under SGAM, shocks to SES are reflected in the DNA of subsequent generations, and the distribution of genetic variants in society is endogenous to economic institutions.

Keywords: Assortative mating, MoBa, UK Biobank.

Introduction

How families are formed, and transmit traits and assets to their offspring, is crucial for understanding inequality and social structure. Assortative mating in marriage markets can increase inequality

between families (Breen and Salazar 2011; Greenwood et al. 2014) and contribute to its persistence across generations, which is surprisingly high (Clark and Cummins 2015; Solon 2018). Wealthy families pass on advantages to their children through both genetic inheritance and environmental influence (Rimfeld et al. 2018; Björklund et al. 2006; Sacerdote 2011).

This paper examines a plausible aspect of marriage markets: both social status and genetics contribute to a person’s attractiveness, and as a result, they may become associated in subsequent generations.¹ For example, suppose that wealth, intelligence and health are advantages in a potential spouse. Then wealthy people are more likely to marry intelligent or healthy people, and their children will inherit both wealth, and genetic variants associated with intelligence or health. We call this mechanism social-genetic assortative mating (SGAM). SGAM may be an important channel for the transmission of inequality. It creates a genetic advantage for privileged families, which may help to explain the long-run persistence of inequality. At the same time, this advantage is not a fact of biology, but is endogenous to the social structure. Indeed, under SGAM, environmental shocks to a person’s social status may be reflected in the genetics of his or her children.

Below, we first write down a theory where attractiveness in the marriage market is a function of both socio-economic status (SES) and genetic variants. We show that social-genetic assortative mating in one generation increases the correlation between SES and genetic variants in the offspring generation. This result provides a new explanation of *genes-SES gradients* – systematic genetic differences between high- and low-SES people (Belsky et al. 2018; Rimfeld et al. 2018; Björklund et al. 2006). The dominant existing explanation for these gradients is meritocratic social mobility: if a genetic variant predicts success in the labour market, then it will become associated with high SES and will be inherited in high-SES families. While under meritocracy, genes cause SES, under SGAM causality also goes from SES to genes.

SGAM also affects patterns of long-run inequality. SES differences between families are much more persistent in the long-run than would be expected from simple parent-child regressions (Clark and Cummins 2015; Barone and Mocetti 2021; Solon 2018). One possible explanation for this is that couples match on an underlying variable, which SES is a noisy measure for. Clark (2023) argues that the data mostly fits a model where this variable is genetic. We show that while SGAM and pure genetic assortative mating (GAM) can both explain persistent inequality, they have different consequences for how inequality responds to policy shocks. Under GAM temporary policy shocks have no long-term effects on inequality, since the underlying genetic variable remains stable within

¹*Social status* refers to characteristics that an individual possesses in virtue of their social position. For example, my wealth is a fact about me that holds in virtue of my relationship to certain social institutions (bank deposits, title deeds et cetera). Other examples include caste, class, income, and educational qualifications. *Socio-economic status* (SES) is a specific type of social status which exists in economically stratified societies, covering variables like educational attainment, occupational class, income and wealth (e.g. White 1982).

families across generations. But under SGAM, shocks affect the distribution of attractiveness in marriage markets and therefore of genetics in the next generation, with lasting effects on inequality.

Next, using data on spouse pairs from two large genetically-informed surveys in Great Britain and Norway, we test the hypothesis that a person’s higher social status attracts spouses with genetic variants predicting greater educational attainment. Our genetic measure, the polygenic score for educational attainment (PSEA), derives from large-scale genome-wide association studies (Lee et al. 2018; Okbay et al. 2022). PSEA reflects a bundle of polygenic effects on underlying traits, including intelligence, personality, and physical and mental health (Demange et al. 2021). PSEA predicts, and causes, educational attainment itself, as well as intelligence and labour market outcomes. It is already known that humans mate assortatively on PSEA (Hugh-Jones et al. 2016; Robinson et al. 2017; Torvik et al. 2022), which makes it a likely candidate for detecting SGAM.

The endogeneity of socio-economic status is the main challenge in identifying the effect of SES on the spouse’s genetic endowment. For instance, people with high educational qualifications tend to also have high PSEA, and as mentioned above, they may take partners based on genetic similarity. Indeed, recent studies show much more assortative mating on PSEA than we would expect if spouses matched only on observed measures of educational attainment (Okbay et al. 2022). To isolate the causal link from own SES to partner’s genes, we use a shock to SES which is independent of own genetics. Specifically, we use a person’s *birth order*. Earlier-born children receive higher parental investment and have better life outcomes, including measures of SES such as educational attainment and occupational status (Black et al. 2011; Booth and Kee 2009; Lindahl 2008). At the same time, the facts of biology, in particular the so-called “lottery of meiosis”, make it likely that siblings’ birth order is independent of their genetic endowments.² Because birth order could affect partner choice through both SES and non-SES mechanisms, we run a mediation analysis similar to Heckman et al. (2013): we estimate a reduced-form model with spouse polygenic scores for educational attainment (PSEA) as the dependent variable, and own birth order as the main independent variable. We then add in to the model measures of own socio-economic status, including university attendance and income. Under certain assumptions, these variables can be interpreted as mediating the effect of birth order on spouse genetics.

In both Great Britain and Norway, later-born children have spouses with significantly lower PSEA in the reduced-form regressions. When we add mediators, including university attendance and/or income, the effect of birth order shrinks substantially, becoming insignificant in Great Britain, while the SES mediators significantly increase the spouse’s PSEA. To interpret this as causal mediation, there must be no unobserved mediators that confound the effect of education. We check this

²In meiosis, each child’s DNA is drawn randomly and independently from their parents’ DNA. If parents choose to have children based on existing children’s genetics, that could threaten this independence assumption: we test for this below. Muslimova et al. (2020) find that PSEA and birth order *interact* to produce human capital.

by including several controls, including non-SES mediators, and a rich set of own genetic traits. Also, within-siblings estimates in the Norwegian sample show that own PSEA significantly affects spouse's education net of family environment and SES. Thus, though it is always possible that an unobserved mediator exists, we believe it is highly plausible that SES is mediating the effect of birth order on spouse genetics.

The effects of individual mediators differ between the two countries. While university attendance explains more than a third of the effects of birth order in both Britain and Norway, income explains about 10% of the effects in Britain but has little or no independent effect in Norway. Although our main focus is on testing the basic mechanism of SGAM, and our Norwegian and British data have different samples and measures, making direct comparisons hard, this is suggestive evidence that in a more egalitarian society, some forms of SES are less important to the marriage market, with long-run implications for genes-SES gradients.

Literature review

Both economists and geneticists study assortative mating. The economics literature has typically focused on educational similarities (e.g. Pencavel 1998; Chiappori et al. 2017) or social class or caste (e.g. Abramitzky et al. 2011; Banerjee et al. 2013), but also sorting based on age, physical traits and ethnicity (Hitsch et al. 2010). Some papers have studied substitution between different traits.³ For instance, Chiappori et al. (2012) showed that individuals trade off BMI for partners' income or education.

Only a few papers have examined assortative mating between socially and genetically inherited traits. Halsey (1958) showed that social mobility combined with assortative mating might increase the association between genetics and social class. Subsequently, some papers in genetics examine cultural transmission, without focusing specifically on inherited social status. Cloninger et al. (1979) model genetic and cultural transmission, where assortative mating is based directly on phenotype and culture is transmitted from parents. Assortative mating, modeled simply as a correlation coefficient, leads culture and genetics to be associated in offspring. Heath and Eaves (1985), following earlier papers (Rao et al. 1976, 1979), introduce "social homogamy", i.e. assortative mating by social background. Otto et al. (1995) allow assortative mating to include both phenotypic and social homogamy.

³Oreffice and Quintana-Domeque (2010) show that height and BMI are associated with spouse earnings. Dupuy and Galichon (2014) find spouse matching on multiple independent dimensions, including education, height, BMI and personality. Chiappori et al. (2021) analyse matching on multiple characteristics and show that a three-dimensional matching model fits their data.

Most recently Rustichini et al. (2023) model intergenerational mobility in the presence of genetically transmitted skills. Spouse matching can depend on skills, income and other characteristics. Genetic stratification on income results. This model overlaps substantially with ours (which was developed independently) though we focus more on policy parameters and have a simpler model of matching. The empirical analysis focuses on estimating intergenerational transmission of income, using a sample of twins and their parents. Rather than examining the matching process directly, they take spouse correlations in income and in polygenic scores from the data.

Modelling SGAM is important for two reasons. First, it can explain the widespread existence of cross-sectional gene-SES gradients. Second, it can explain long-run intergenerational mobility.

Regarding cross-sectional gene-SES gradients: from twin studies, the heritability of occupational class and educational attainment, i.e. the proportion of variance explained by genetic differences between individuals, is around 50% (Tambs et al. 1989). The family socio-economic status of 2-year-old children can be predicted from their genes (Trzaskowski et al. 2014). Children born into higher-income families have more genetic variants predicting educational attainment (Belsky et al. 2018). Adoption studies show that both post-birth environment and pre-birth conditions (genetics and prenatal environment) contribute to the transmission of wealth and human capital (e.g. Björklund et al. 2006). There is also a genes-SES gradient in genetic predictors of health. DNA-derived scores predicting several health outcomes are associated with regional economic deprivation (Abdellaoui et al. 2019). The correlation between education and health may be mediated by shared genetic causes (Amin et al. 2015; Boardman et al. 2015). Family SES correlates with several health-related polygenic scores (Selzam et al. 2019), and genetic variants associated with SES may explain the genetic correlations between many mental health outcomes (Marees et al. 2021).

SGAM shows how marriage markets can lead high SES to be associated with different genetic variants, i.e. it can explain genes-SES gradients. Geneticists call this phenomenon social stratification. An alternative explanation is returns to human capital in labour markets. Higher-ability parents reap higher market returns, and they may then pass both higher socio-economic status and their genes to their children (Belsky et al. 2018).⁴ This mechanism depends on meritocratic social institutions (Branigan et al. 2013; Heath et al. 1985): in a society where social status was ascribed rather than earned, it could not take effect. Indeed, after the fall of communism in Estonia, the heritability of SES increased, presumably because post-communist society allowed higher returns to talent (Rimfeld et al. 2018). By contrast, SGAM does not require meritocracy. Since meritocracy is historically rare, while assortative mating is universal, this suggests that genes-SES gradients are likely to be historically widespread.

⁴Belsky et al. (2018) offer three reasons for the association between education-linked genetic variants and SES, but do not mention SGAM.

Regarding long-run mobility: long-run estimates of intergenerational persistence of wealth and status are surprisingly higher than would be predicted from parent-child correlations (Clark and Cummins 2015; Barone and Mocetti 2021; Solon 2018), and distant relatives in the same generation are also more similar than parent-child and spousal correlations would predict (Collado et al. 2023). Clark (2023) argues that unobserved genetic variation determines social status, and mating is purely on this unobserved “social competence”. This is a model of pure genetic assortative mating (GAM).

Both GAM and SGAM models lead to long-run intergenerational persistence, and to cross-sectional gene-SES gradients. However, their predictions of the effects of policy are quite different. Under GAM, families continue to mate on social competence, irrespective of its relationship to status. So, temporary policy shocks don’t have long-lasting effects. For example, Alesina et al. (2020) show that elite households lost their status during the Chinese Communist revolution, but regained it after the rise of Deng Xiaoping. This is compatible with genetically-transmitted social competence (but also with culturally transmitted values). Under SGAM, a shock that reduces elite families’ SES will be reflected in marriage markets, and ultimately in their children’s genetics. As a result, short run policy changes have long-lasting effects (see Figure 3 below).

Because quite different models can lead to similar observable correlations, it can be hard to pin the true model down from the data. As Okbay et al. (2022) put it: “Because the parameters of a general biometric model cannot be separately identified from a small number of phenotypic correlations among different types of relatives, researchers typically have to assume that some of the parameters equal zero in order to estimate other parameters.” For example, Collado et al. (2023) derive extremely low estimates for heritability of education, within a model in which all genetic similarity between spouses is driven by matching either on the measured phenotype, or on a shared cultural factor; Torvik et al. (2022) estimate partner correlation between “true” polygenic scores for education of 0.37, and heritability above 50%, in a model where environment is shared between siblings but not across generations; while Clark (2023) argue for a purely genetic model with no cultural inheritance.

This motivates us to use a different approach. We cleanly identify separate environmental and genetic contributions to assortative mating: environmental contributions using birth order, genetic contributions by comparing polygenic scores within siblings. This lets us rule out pure GAM, as well as pure mating on SES. In fact, we find large effects of birth order on spouse polygenic scores, equivalent to more than half a standard-deviation shift in one’s own polygenic score, in both Britain and Norway.

Model

People in the marriage market have two characteristics: $x = (x_1, x_2)$, drawn from a normal distribution

$$\mathcal{N} \begin{pmatrix} 0 & s^2 & \sigma \\ 0 & \sigma & S^2 \end{pmatrix}.$$

We interpret x_1 as a genetic measure, for example of genetic variants predicting height, physical attractiveness, health or intelligence. x_2 is a measure of socio-economic status, such as income or wealth, or social status more generally (we sometimes use “wealth” as a shorthand).

People’s attractiveness is given by

$$i(x) = ax_1 + (1 - a)x_2$$

where $a \in [0, 1]$ is a parameter reflecting the relative importance of genetics to wealth in the marriage market.⁵ If $a = 0$, marriage markets are highly inegalitarian, such that only SES matters. If $a = 1$, marriage markets are economically egalitarian and only genetics matter. We expect realistic societies to fall between these extremes, with $0 < a < 1$. Then, both genes and SES matter to attractiveness, and as a result, social-genetic assortative mating (SGAM) takes place. This model does not assume that people match *directly* on genetics, which most observers agree would be unlikely. Instead, genetics and SES both contribute to an attractiveness phenotype, which is matched on. Attractiveness is a deterministic function of genes and SES, but both genes and SES have random shocks in each generation (see below). Adding a random component to attractiveness itself would likely retain the basic insights of our model whilst reducing the effects of SGAM on genes-SES correlation.

Attractiveness i is distributed $N(0, \sigma_I^2)$, where

$$\sigma_I^2 = a^2 s^2 + (1 - a)^2 S^2 + 2a(1 - a)\sigma.$$

People form matches with transferable utility, where the surplus for a match between x and y is $S(i(x), i(y))$ such that $\partial^2 S / \partial i \partial j > 0$, i.e. S is supermodular. As a result there is positive assortative mating on attractiveness: x matches with y only if they are at the same quantile of attractiveness, i.e. if $i(x_1, x_2) = i(y_1, y_2)$. Within attractiveness quantiles, matching is random. This is the SGAM mechanism.

⁵Note that since the variance of the shocks to x_1 and x_2 (see below) has been normalized to 1, a also reflects this variance. That is, a large variance of SES shocks (compared to genetic shocks) translates into a being large.

Our first proposition shows that if SGAM is taking place, i.e. if $0 < a < 1$, then there is a positive correlation between one partner's wealth and the other partner's genetics.

Proposition 1. *Under SGAM, the distribution of couples' characteristics is normal, with mean 0 and covariance matrix*

$$\mathbb{C} \begin{pmatrix} x_1 \\ x_2 \\ y_1 \\ y_2 \end{pmatrix} = \begin{pmatrix} s^2 & \sigma & A^2 & AC \\ \sigma & S^2 & AC & C^2 \\ A^2 & AC & s^2 & \sigma \\ AC & C^2 & \sigma & S^2 \end{pmatrix} \quad (1)$$

where:⁶

$$A = \frac{as^2 + (1-a)\sigma}{\sqrt{a^2s^2 + (1-a)^2S^2 + 2a(1-a)\sigma}} = \frac{as^2 + (1-a)\sigma}{\sigma_I};$$

$$C = \frac{a\sigma + (1-a)S^2}{\sqrt{a^2s^2 + (1-a)^2S^2 + 2a(1-a)\sigma}} = \frac{a\sigma + (1-a)S^2}{\sigma_I}.$$

In particular, the covariance between x_2 and y_1 , AC , is positive if either x_1 and x_2 are already correlated ($\sigma > 0$), or if they are uncorrelated ($\sigma = 0$) and the attractiveness parameter a is strictly between 0 and 1.

Proof. See Appendix. □

We consider the distribution of couples' wealth. Under random matching (see the Appendix) this has mean 0 and variance $2S^2$. Under SGAM, the variance is:

$$V(x_2 + y_2) = 2S^2 + 2C^2 \geq 2S^2$$

with strict inequality if $a < 1$ or $\sigma > 0$. The variance is decreasing in a and equals $4S^2$ if $a = 0$. Thus, SGAM increases cross-sectional inequality, but less so than pure matching on wealth.

⁶ A and C are not related to the ACE model in genetics.

Children

All couples have the same number of children. A child's characteristics are given by:

$$\begin{aligned} x'_1 &= \frac{\tau}{2}(x_1 + y_1) + \varepsilon \\ x'_2 &= \frac{\theta}{2}(x_2 + y_2) + \eta \end{aligned} \tag{2}$$

where x and y are the child's parents, and ε and η are independent normal random shocks with mean 0 and variance 1.

Parameter $\tau \approx 1$ reflects genetic inheritance. Under standard biological assumptions $\tau = 1$ and characteristics show no regression to the mean. In our model this leads the variance of x_1 to grow without limit over generations. In reality, we expect $\tau < 1$ because very extreme characteristics are selected against, a process known as stabilizing selection (Schmalhausen 1949; Sanjak et al. 2018).

Parameter $\theta \in [0, 1]$ reflects inheritance of SES. Unlike τ it may vary between societies. θ is high when there is high intergenerational transmission of SES. Among other things, θ captures social and economic institutions that affect this intergenerational transmission, from taxation and public education to hereditary nobility. If we interpret x_2 narrowly as wealth, $1 - \theta$ can be thought of as the rate of inheritance tax.

For the time being, we assume that a person's genetic endowment has no impact on their SES. Technically, thus, x'_2 does not directly depend on x'_1 . In a meritocratic society we would expect adult SES to partly depend on genetics. We show that even absent meritocracy, correlations between x'_1 and x'_2 can arise. In the Appendix, we relax this assumption and allow meritocracy.

We can now calculate the covariance matrix for $x' = (x'_1, x'_2)$ under SGAM as:

$$\begin{aligned} \mathbb{C} &= \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \begin{pmatrix} \frac{\tau}{2} & 0 & \frac{\tau}{2} & 0 \\ 0 & \frac{\theta}{2} & 0 & \frac{\theta}{2} \end{pmatrix} \begin{pmatrix} s^2 & \sigma & A^2 & AC \\ \sigma & S^2 & AC & C^2 \\ A^2 & AC & s^2 & \sigma \\ AC & C^2 & \sigma & S^2 \end{pmatrix} \begin{pmatrix} \frac{1}{2}\tau & 0 \\ 0 & \frac{1}{2}\theta \\ \frac{1}{2}\tau & 0 \\ 0 & \frac{1}{2}\theta \end{pmatrix} \\ &= \begin{pmatrix} \frac{1}{2}A^2\tau^2 + \frac{1}{2}s^2\tau^2 + 1 & \frac{1}{2}\theta\sigma\tau + \frac{1}{2}AC\theta\tau \\ \frac{1}{2}\theta\sigma\tau + \frac{1}{2}AC\theta\tau & \frac{1}{2}C^2\theta^2 + \frac{1}{2}S^2\theta^2 + 1 \end{pmatrix} \end{aligned} \tag{3}$$

We now explore two issues. First, under SGAM, genetic characteristics are no longer exogenous; because of assortative matching, they are (partly) socially determined. In particular, even if genetics and SES are uncorrelated among parents, the expected genetic endowment of the child is positively related to parental SES. Second, as a result, in the long run a correlation appears between traits; that is, high SES people inherit genes that are attractive in marriage markets.

Regarding point 1, we compute the expected genetic characteristic of the child, conditional on parental wealth:

$$\mathbb{E} \left[\frac{\tau}{2} (x_1 + y_1) + \varepsilon \mid x_2 = v, y_2 = w \right] \quad (4)$$

Given the symmetry of the model, this conditional expectation only depends on the parents' total wealth, i.e. $v + w$.

Claim 1. *Under SGAM, if $\sigma = 0$ (i.e. genetics and SES are uncorrelated for the parents), then the expected genetic endowment of the children (4) is linearly increasing in parental SES. The relationship increases with the ratio of genetic variance to SES variance (s^2/S^2), is zero for $a = 0$ or $a = 1$, and is highest for intermediate values of a .*

Next, we study the correlation between children's traits 1 and 2 as a function of σ , the covariance of parents' traits.

Claim 2. *Under SGAM, if genetics and SES are uncorrelated for the parents, then they are positively correlated for the children so long as $0 < a < 1$. The correlation is increasing in θ .*

Whether characteristics are more or less correlated for children than for parents depends on whether the initial correlation between parents' characteristics is larger or smaller than the asymptotic one, derived below.

Figure 1 shows the intuition behind the model. Parents match on downward-sloping attractiveness isoquants given by $ax_1 + (1-a)x_2 = u$. Their children are in between them on both dimensions. This compresses the distribution along the attractiveness isoquants, which leads to a positive correlation between genetics and SES. The correlation between x'_1 and x'_2 is 0 when $a = 0$ or $a = 1$, because then spouses don't trade off SES for genes. It is highest for intermediate values of a .

These results show that SGAM can lead to a genes-SES gradient, i.e. a positive correlation between genes and SES. Also, the strength of the genes-SES correlation is affected by economic institutions, insofar as these are captured in θ . When θ is high, the genes-SES correlation is high too.

We now consider the asymptotic distribution of x_1 and x_2 when the matching process is repeated over many generations. As we would expect, our main results continue to hold.

Figure 1: Theory. The shaded area is the population distribution. Parents (solid circles) match along attractiveness isoquants (dotted lines). Children (hollow circles) are between them. As a result, the children's distribution is squeezed along attractiveness isoquants, and x_1 and x_2 become associated.

Proposition 2. *Under SGAM, for $\theta < 1$ and $\tau < 1$, the dynamics converge to a stationary distribution that is normal with mean zero and covariance matrix*

$$\mathbb{C} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} \bar{s}^2 & \bar{\sigma} \\ \bar{\sigma} & \bar{S}^2 \end{pmatrix}$$

where $\bar{s}, \bar{S}, \bar{\sigma}$ are functions of the parameters (a, θ, τ) . Moreover, the asymptotic correlation between characteristics, $\text{corr} = \bar{\sigma} / \bar{s} \bar{S}$, is non-negative, positive for $0 < a < 1$, increasing in θ and increasing then decreasing in a . The coefficient of parents' wealth on children's genetics is also positive for $0 < a < 1$.

For $\theta = 1$, the dynamics diverge and $\bar{S}^2$ goes to $+\infty$; for $\tau = 1$, the dynamics diverges and $\bar{s}^2$ goes to $+\infty$.

Figure 2 plots the asymptotic squared correlation between x_1 and x_2 . In genetic terms, this is the heritability of SES. It is maximized for intermediate levels of a . Note that both $\bar{S}^2$ and $\bar{\sigma}$, as well as the correlation between characteristics and the conditional expectation of genetics given wealth, are increasing in θ . Higher transmission of SES increases inequality of SES in equilibrium (unsurprisingly), but also the heritability of SES.

Figure 2: Long-run squared correlation between genetics x_1 and SES x_2 (heritability of SES), by weight of genetics in spouse matching (a) and strength of direct transmission of SES (θ). $\tau = 0.95$.

Extensions

In modern meritocracies, people's adult SES depends not just on their parents' social status and on chance, but also on their own effort and skills, which might be related to their genetics. So let

$$\begin{aligned} x'_1 &= \tau \frac{x_1 + y_1}{2} + \varepsilon \\ x'_2 &= \gamma x'_1 + \theta \frac{x_2 + y_2}{2} + \eta \end{aligned} \tag{5}$$

where $\gamma > 0$ represents the effect of own genetics on own SES. γ can be thought of as measuring meritocratic mobility, but alternatively as the degree of overlap between genes that matter in marriage and labour markets. The basic result continues to hold, and also, γ increases the correlation between genes and SES.

Proposition 3. *Under SGAM and equation (5), if genetics and SES are uncorrelated for the parents, then they are positively correlated for the children so long as $0 < a < 1$ or $\gamma > 0$. The correlation is increasing in γ . Also, so long as $\gamma > 0$ and either $0 < a < 1$ or $\sigma > 0$, the coefficient of parents' wealth on children's wealth exceeds θ .*

With this extension, we can examine how intergenerational transmission of inequality responds to policy shocks under different models of assortative mating. Figure 3 simulates different generations of families under a policy shock which reduces θ and γ to 0 for one generation. We group families into quartiles by their SES on the eve of the shock, and track the quartiles' mean SES over generations. The left panel shows pure genetic assortative mating ($a = 1$). Since couples only match on genetics, although the shock temporarily reduces SES differences to zero, afterwards families return to where they would have been without the shock (dashed lines). The right panel shows SGAM with $a = 0.3$. Here, the shock reduces the mating value of previously high-SES individuals, and as a result, their SES never recovers to its no-shock value.

In the Appendix we consider further extensions. We allow men and women to have different values of a , i.e. different weights on genetics and SES in the attractiveness function. Lastly, we show that our basic result is robust to allowing non-normal distributions of x_1 and x_2 and non-linear attractiveness functions.

Other extensions are possible. We assumed that all couples have the same number of children. If fertility increased with x_1 or x_2 , we would expect this to reduce the variance of traits in the children's generation and possibly also their covariance. Here, matching preferences, summarized by the a parameter, are exogenous; it would be natural to model a as an equilibrium outcome. For

Figure 3: A simulated policy shock under GAM ($a = 1$) and SGAM ($a = 0.3$). Lines show mean SES in each quartile of families, grouped by SES in the generation before the shock. In generation 0, θ and γ are reduced to zero. Thereafter they return to their previous values ($\theta = 0.8, \gamma = 0.1$). Under GAM, family SES returns to the no-shock counterfactual (dashed lines). Under SGAM it never does so.

example, if parents care about their children’s wealth, a might decrease in θ . Indeed, below we see suggestive evidence that income is valued differently in Norwegian and British marriage markets. Finally, if different individuals have varying matching preferences (values of a), the model becomes hard to work with because there is no agreed-upon ranking of men and women, but computations using the Gale-Shapley matching algorithm shows that the basic insights of SGAM still hold.⁷

Discussion

The meanings of both social status, and “good genes” in the marriage market, are likely to vary across societies. Social status could encompass variables like social class or caste; ethnic identity in “ranked” ethnic systems; or in modern societies, SES, including wealth, income and occupation. Regarding genetics, standards of physical attractiveness, and other genetically-influenced characteristics which make someone a “good match”, vary across societies and over time. The central prediction of the model is that whatever those characteristics, in the long run they will become correlated with SES.

Recent empirical work shows high persistence of SES over time, in particular at the top. Clark (2023) argues that this could be explained by unobserved genetic variation. Proposition 3 shows that if genes affect own wealth directly, under assortative mating, the regression coefficient of parents’ wealth on own wealth exceeds the “direct” coefficient θ , because parents’ wealth correlates with parents’ genetics and via that with own wealth. Thus, regressions of wealth on wealth may include the effect of unobserved genetic variation. This may be a confound due to pre-existing gene-SES correlation (if $\sigma > 0$). But under SGAM ($0 < a < 1$) it can also be a mediating variable, since changes in someone’s wealth may indeed affect the identity of their spouse, hence the genetics of their offspring, and from that their offspring’s adult wealth.

The converse also holds: regressions of children’s characteristics on their genetics alone risk overestimating the effect of genetics, by confounding it with the effects of correlated socio-economic status. Recent work in genetics has shown this. Polygenic scores for educational attainment have smaller effects in between-sibling regressions, where between-family variation in SES is partialled out and where genetic variants are guaranteed to be randomly allocated, than in regressions which pool the whole sample (Howe et al. 2022). Parents’ genetic variants which are *not* passed on to children predict children’s characteristics, partly due to social stratification in the geneticists’ sense of non-random mating (Kong et al. 2018; Young 2023).

The model predicts variation in the effects of SGAM. In particular, in “caste societies” where there is complete endogamy within social status groups, there is no scope for SGAM, because marriage

⁷See <https://github.com/hughjonesd/trading-status-genetics/blob/main/gale-shapley-multiple-a.R>.

partners do not trade off genetics for social status ($a = 0$). Also, the association between genes and SES is increased by the institutional variable θ , which captures intergenerational persistence of SES. This implies that policy has long-run effects on biosocial structure: reducing θ not only increases intergenerational mobility, but reduces the correlation of genes with SES, and hence the bias of what Harden (2021) calls the “genetic lottery”. Conversely, reforms that increase meritocracy (γ , Proposition 3) may strengthen the genes-SES gradient. This poses the problem raised by Young (1958) and more recently Markovits (2019): meritocracy may be self-limiting or even self-undermining.

Data and methods

The central insight in our model is that higher SES and “good genes” assort in the marriage market. We wish to test this directly, i.e. to test whether $0 < a < 1$ in the attractiveness equation

$$i(x) = ax_1 + (1 - a)x_2$$

where x_2 is social status and x_1 is genetic endowment. Consider the effect of a change in x_2 holding x_1 constant. If $a = 1$ then this will not change $i(x)$ and therefore will not change the expected characteristics of the spouse. So, if we regress spouse’s x_1 on own x_2 , and reject the null of no effect, we can reject $a = 1$.⁸ In other words, we set out to test the central assumption in our model that marriage markets weigh both SES and genetics, by testing its implication, i.e., that individuals with higher SES have spouses with higher genetic scores (PSEA).

We use data from two sources: Great Britain and Norway. This allows us to check our basic result in two different societies, and also to make (tentative) comparisons between them. Our Great Britain data comes from the UK Biobank, a study of about 500,000 individuals born between 1935 and 1970 (Bycroft et al. 2018). The Biobank contains information on respondents’ genetics, derived from DNA microarrays, along with questionnaire data on health and social outcomes. The Biobank does not contain explicit information on spouse pairs. We categorize respondents as pairs if they had the same home postcode on at least one occasion;⁹ both reported the same homeownership/renting status, length of time at the address, and number of children; attended the same UK Biobank assessment center on the same day; both reported living with their spouse (“husband, wife

⁸Conceivably, if $a = 0$ but there is a pre-existing correlation between x_1 and x_2 in the population, then an increase in own x_2 will increase spouse’s expected x_2 and therefore spouse’s expected x_1 , even though the latter does not enter the attractiveness equation. We can separately test the null that $a = 0$ by regressing spouse’s x_2 on own x_1 , holding own x_2 constant. Existing work has already linked own genetics to spouse’s SES, e.g. education, so we focus on the other direction and treat this direction as a robustness check below.

⁹A typical UK postcode contains about 15 properties.

or partner”); and consisted of one male and one female. We also eliminate all pairs where either spouse appeared more than once in the data. This leaves a total of 35,682 pairs.¹⁰

Our Norway data comes from the Norway Mother, Father and Child Cohort Study (MoBa), a population-based study of pregnant women and their partners and children (Magnus et al. 2016; Paltiel et al. 2014). Participants were recruited from all over Norway from 1999-2008. 41% of women consented to participation. In this paper, we use about 100,000 genotyped individuals and about 45,000 genotyped spouse pairs. The Norway data has some advantages over UK Biobank, including higher participation, larger sample size, and spouse pairs which are known rather than inferred. On the other hand it is missing some variables, including IQ measures and self-reported health.

Our key dependent variable is spouse’s *Polygenic Score for Educational Attainment* (PSEA). A polygenic score is a DNA-derived summary measure of genetic risk or propensity for a particular outcome, created from summing small effects of many common genetic variants, known as Single Nucleotide Polymorphisms (SNPs). We focus on PSEA rather than other polygenic scores for two reasons. First, educational attainment plays a key role in human mate search. People are attracted to educated potential partners (Buss and Barnes 1986; Belot and Francesconi 2013); spouse pairs often have similar levels of educational attainment, as well as similar PSEA (Vandenberg 1972; Schwartz and Mare 2005; Greenwood et al. 2014; Hugh-Jones et al. 2016; Torvik et al. 2022). Second, PSEA predicts a set of important socioeconomic variables, including not only education but also social and geographic mobility, IQ, future income and wealth (Belsky et al. 2016; Barth et al. 2020; Papageorge and Thom 2020).¹¹

PSEA in the UK was calculated using per-SNP summary statistics from Lee et al. (2018), re-estimated excluding UK Biobank participants; in Norway, using statistics from Okbay et al. (2022). The score was normalized to have mean 0 and variance 1. Because polygenic scores are created from estimates of many small effects, they contain a large amount of noise relative to the true best estimator that could be derived from genetic data. For instance, PSEA explains only 11–13% of variance in educational attainment (Lee et al. 2018), whereas the true proportion explained by genetic variation – the heritability – is estimated from twin studies to be about 40% (Branigan et al. 2013). Also, polygenic scores are no more guaranteed to be causal than any other independent variable. For example, social stratification by ancestry may lead genes to be associated with educational attainment even if they play no causal role (Selzam et al. 2019).

Despite these points, PSEA has non-trivial estimated effects on educational attainment. PSEA

¹⁰In the appendix, we test the validity of our matching process by counting the proportion of pairs who had a shared genetic child, in a subsample of the data. We also check whether any misidentified pairs might have biased our results, by constructing a dataset of “known fake pairs”.

¹¹See Papageorge and Thom (2020) for a detailed discussion of polygenic scores aimed at economists.

correlates with measures of education, including university attendance and years of full-time education. Effect sizes are smaller but still non-trivial in within-siblings regressions (Lee et al. 2018), where they can be interpreted as causal, since genetic variation across siblings is guaranteed to be random by the biological mechanism involved – the “lottery of meiosis” (see below). We recheck these facts within the UK Biobank sample. In a simple linear regression ($N = 408,524$) of university attendance on PSEA, a one-standard-deviation increase in PSEA was associated with a 9.2 percentage point increase in the probability of university attendance ($p < 2 \times 10^{-16}$). In a within-siblings regression among genetic full siblings ($N = 35,879$), the increase was 4.5 percentage points ($p < 2 \times 10^{-16}$). This suggests that about half of the raw correlation of PSEA with university attendance is down to environmental confounds like parental nurture, while the remainder is causal (cf. Lee et al. 2018). Still, the causal effect remains substantial: for a rough comparison, the (ITT) effect on college attendance of the Moving To Opportunity experiment in the US was 2.5 percentage points (Chetty et al. 2016).

We use two measures of socio-economic status: income, and university attendance. Income is a direct measure of SES. University attendance is a predictor of income over the whole life course, and a form of SES in itself. The MoBa data includes both university attendance and income. UK Biobank includes university attendance, but only has a direct measure of current household income, which is inappropriate for our purposes because it includes income from both spouses and is measured after marriage. Instead, we estimate income in the respondent’s first job, by matching the job’s Standard Occupational Classification (SOC) code with average earnings by SOC from National Statistics (2007). Job codes are only available for a subset of respondents. We convert income to a z score among each group of respondents with the same gender and year of birth.

Figure 4 illustrates the core idea of SGAM within the UK Biobank data. The X axis shows a measure of one partner’s socio-economic status: university attendance or income. The Y axis plots the other partner’s mean PSEA. Both males and females who went to university had spouses with higher PSEA. So did males and females with higher income in their first job. Since DNA is inherited, these people’s children will also have higher PSEA.¹²

These plots do not prove that SGAM is taking place. Since an individual’s own PSEA correlates with both their educational attainment, and their income, both figures could be a result of genetic assortative mating (GAM) alone (Hugh-Jones et al. 2016). Indeed, recent studies show much higher levels of GAM than could be explained by matching on the observed education phenotype alone (Okbay et al. 2022). To demonstrate SGAM, we need a source of social status which is exogenous to genetics. Also, the link between social status and spouse genetics is likely to be noisy, for three reasons: first, polygenic scores contain a large amount of error, as discussed above; second,

¹²Figure 5 in the appendix shows the same plot for the MoBa sample.

Figure 4: Spouse polygenic score for educational attainment (PSEA) against own university attendance and own income in first job (Great Britain). Lines show 95% confidence intervals. PSEA is normalized to have mean 0 and variance 1. Income is estimated from the respondent's first job, as the average income of the SOC job code.

causal mechanisms behind variation in social status are likely to be noisy; third, to paraphrase Shakespeare (1595), the spouse matching process is highly unpredictable. So, we need a large N to give us enough power. This rules out time-limited shocks such as changes to the school leaving age (Davies et al. 2018).

We use *birth order*. It is known that earlier-born children receive more parental care and have better life outcomes, including measures of SES such as educational attainment and occupational status (Lindahl 2008; Booth and Kee 2009; Black et al. 2011).¹³ On the other hand, all full siblings have the same *ex ante* expected genetic endowment from their parents, irrespective of their birth order. This is supported by the biological mechanism of meiosis, which ensures that any gene is transmitted from either the mother or the father to the child, with independent 50% probability (Mendel 1865; Lawlor et al. 2008). For example, siblings' expected polygenic score is equal to the mean of their parents' polygenic scores. We can therefore use birth order as a “shock” to social status. “Shock” is in quotes because we do not claim that birth order is exogenous to all other variables. For example, it naturally correlates with parental age, and it may also correlate with household SES at the time of birth. We only claim that birth order is exogenous to genetic variation.

Although birth order within a given family is independent of genetics, birth order in the whole sample might be correlated with other environmental and genetic factors. In particular, birth order naturally correlates with family size, i.e. the total number of siblings born, because e.g. third-born children must be in a family of at least three siblings. It also correlates with parental age, which may affect the income and maturity of the parents. There are also potential genetic effects from parental age (Cochran and Harpending 2013), though recent research has rejected these in favour of “social” explanations (Kristensen and Bjerkedal 2007; Black et al. 2011). To control for family size, we use dummies for each possible value of family size. In most regressions, we use only respondents with between 1 and 5 siblings, i.e. with a family size of 2-6: beyond that, estimation would get noisy because of small cell sizes. To control for parental age, we use father's and/or mother's age at the respondent's birth, because we often have data only for one parent. We use the mean if we have both parents. In the UK Biobank, this data is only available if the respondent's parent was still alive. For other controls we use respondent's month of birth, year of birth, and own PSEA. Our claim is that controlling for these variables, birth order is independent of genetic

¹³Earlier work was ambiguous on the effects of birth order (e.g. Hauser and Sewell 1985; Hanushek 1992). However, this work often used unrepresentative samples and/or did not control for family size or parental age. More recent work improves on this and shows clear birth order effects. Kantarevic and Mechoulam (2006) show that parental age is an important confound for birth order. Black et al. (2005) show substantial birth order effects in the whole Norwegian population, even in a family fixed-effects specification, and after controlling for mother's age. Booth and Kee (2009) examine UK families, controlling for family size and for parental age at birth, and show significant and substantial birth order effects on education. Some studies (e.g. Black et al. 2005; De Haan 2010) use twin births or the gender mix of children as instruments for family size. They too typically find that birth order has large negative effects.

variation.

Decomposing the birth order effect on spouse genetics

Birth order offers a way to test the central assumption in our theoretical model – that SES is traded for genes in the marriage markets – by providing a shock to SES which is exogenous to own genetics. Ideally, we might prefer to use birth order as an instrument for SES. However, our measures of social status are noisy and incomplete. For example, we know whether subjects attended university, but not which university. Birth order likely affects both measured and unmeasured aspects of SES. So, an instrumental variables approach would fall foul of the exclusion restriction.

Instead, we conduct a mediation analysis, following the strategy of Heckman et al. (2013). We first confirm that birth order affects our measures of respondents’ SES (income and education). Then, we regress spouse’s PSEA on birth order, with and without controlling for SES. Under the assumption that birth order is exogenous to own genetics, these regressions identify the effect of birth order, plus other environmental variables that correlate with it, on own social status and spouse’s genetics. Most importantly, if the estimated effect of birth order on spouse’s PSEA changes when SES is controlled for, that is evidence that SES mediates the effect of birth order.

We follow Heckman et al. (2013) to decompose the aggregate treatment effect into components due to observed and unobserved proximate channels affected by the treatment. Our aim is to estimate the effect of SES (as an effect of birth order) on spouse PSEA.

Assume B is a multivalued variable indicating birth order. Let Y_b be the counterfactual outcome (spouse PSEA) for the first-born, second-born etc. Given b , spouse PSEA is assumed to be independent across observations conditional on some predetermined controls which are assumed not to be affected by B .

Let m_b be a set of mediators, i.e. proximate outcomes determined by b , which account (at least in part) for the b treatment effect on spouse PSEA. We can think of m_b as all the effects on attractiveness, such as increments to SES, health, cognitive and non-cognitive skills, that individuals receive due to their birth rank. We can split the mediators in m_b into a set J_m of measured mediators, including university attendance and income in first job, and a set J_u of mediators that we cannot measure.

Our linear model is:

$$Y_b = \kappa_b + \sum_{j \in J_m} \alpha_b^j m_b^j + \sum_{j \in J_u} \alpha_b^j m_b^j + \mathbf{X}' \beta_{\mathbf{b}} + \tilde{\varepsilon}_b = \tau_b + \sum_{j \in J_m} \alpha_b^j m_b^j + \mathbf{X}' \beta_{\mathbf{b}} + \varepsilon_b \quad (6)$$

where $\tilde{\varepsilon}_b$ is a mean-zero residual assumed independent of m_b and $\mathbf{X}$; $\tau_b = \kappa_b + \sum_{j \in J_u} \alpha_b^j E(m_b^j)$; and $\varepsilon_b = \tilde{\varepsilon}_b + \sum_{j \in J_u} (m_b^j - E(m_b^j))$. We simplify by assuming that $\beta_b = \beta$ and $\alpha_b = \alpha$ for all b , i.e. that the effects of $\mathbf{X}$ and m_B don't differ by birth order.¹⁴ We assume differences in unmeasured investments due to b are independent of $\mathbf{X}$.

We use a linear model for each observed mediator variable:

$$m_b^j = \mu_{0,j} + \mathbf{X}' \boldsymbol{\mu}_{1,j} + \mu_{2,j} \cdot b + \eta_j, j \in J_m \quad (7)$$

where η_j is a mean-zero residual. We also assume the treatment-specific intercepts are linear in b :

$$\tau_b = \tau_0 + \tau b. \quad (8)$$

With the simplifying assumptions above and substituting (7) and (8) into (6) we obtain:

$$Y_b = \tau_0 + \tau b + \sum_{j \in J_m} \alpha^j (\mu_{0,j} + \mathbf{X}' \boldsymbol{\mu}_{1,j} + \mu_{2,j} \cdot b + \eta_j) + \mathbf{X}' \boldsymbol{\beta} + \varepsilon_b \quad (9)$$

Using equation (9), we can decompose the average treatment effect of a change from birth order b to b' into the effect of measured mediators m^j and unmeasured mediators on the outcome:

$$E(Y_{b'} - Y_b) = \tau(b' - b) + \underbrace{\sum_{j \in J_m} \alpha^j E(m_{b'}^j - m_b^j)}_{\text{Direct effect + unmeasured mediators}} + \underbrace{\sum_{j \in J_m} \alpha^j \mu_{2,j} (b' - b)}_{\text{Effect of measured mediators}} \quad (10)$$

We are primarily interested in estimating the effect of SES on spouse PSEA, amongst the measured mediators. If this effect is significantly different from zero, it implies that $(1 - a)$ is different from zero in our attractiveness equation, and therefore a is different from 1. Furthermore, we would like to measure the relative importance of SES compared to other factors in predicting spouse PSEA.

We therefore estimate:

$$Y = \tau_0 + \tau B + \sum_{j \in J_m} \alpha^j m_b^j + \mathbf{X}' \boldsymbol{\beta} + \varepsilon \quad (11)$$

¹⁴Under the assumption that measured and unmeasured mediators are uncorrelated, we can test these assumptions by running an OLS regression of an extended model (11) where we interact the measured mediators and controls with the treatment B , and test the significance of the coefficients on the interaction terms ($\alpha_b = 0$ and $\beta_b = 0$). See Heckman et al. (2013) and Fagereng et al. (2021) for details and different applications. When we run the model with interactions, only one interaction is significant after Bonferroni correction at $p < 0.05/34$: the interaction of income in first job with the dummy for birth order 6. So overall, the uninteracted model seems a good enough approximation.

Estimating the above by OLS will generate unbiased estimates of α^j if m^j is measured without error and is uncorrelated with the error term ε . Since ε contains both individual disturbances and differences in unmeasured investments due to birth order, there are two identifying assumptions that need to hold for unbiased OLS estimates: (a) the measured investments (specifically SES) should be independent of unmeasured investments generated by birth order. Failing this, the estimates of α^j will be conflated with the effects of unmeasured investments. Second, (b) the measured investments should be uncorrelated with other shocks $\tilde{\varepsilon}_b$. With respect to assumption (a), in our regressions we control for a set of potential alternative mediators available in the data: height, BMI, and (in UK Biobank only) fluid IQ and self-reported general health. With respect to assumption (b), we use further controls, such as parental age, year of birth, and own PSEA, to reduce unobserved variation in the error term.

By running a least square regression of (11), we can estimate τ and α^j . If the assumptions above hold and the estimated α^j is significantly different from zero, we have evidence that the parameter a in the attractiveness equation is different from 1. If assumption (a) holds, the part of the birth order treatment effect on spouse PSEA that is due to measured mediators, including SES, can be constructed using the estimated α^j and the effects of birth order on measured mediators. We can estimate these effects from OLS regressions based on equation (7) for each measured mediator (in particular university attendance and income) on $\mathbf{X}$ and B . The part of the birth order effect that is due to university attendance (or income) on spouse PSEA will be the coefficient of university/income in the regression of spouse PSEA in equation (11), multiplied by the coefficient of birth order on university/income from equation (7). We now apply this framework to each of our two samples.

Results: Great Britain

We first regress our measures of socio-economic status, university attendance and income from first job, on birth order in the UK Biobank spouse pairs. We also do the same for four non-SES mediators that could be affected by birth order: fluid IQ, height, body mass index (BMI) and a measure of self-reported health. We control for respondent's own PSEA and their parents' age at birth (see below). Table 1 shows that birth order significantly predicts all the mediators. Effects are quite substantial: on average, one extra elder sibling reduces the chance of attending university by about 7.9 percentage points, income by about 0.077 standard deviations, fluid IQ by about 0.27 points on a 13 point test, height by about 0.7 centimeters, and self reported health by 0.043 points on a 4-point scale; and increases BMI by 0.19.

Next we run regressions of spouse PSEA on birth order. Table 2 reports the results. Column 1

reports results controlling only for family size (using dummies). As expected, higher birth order is negatively associated with spouse's PSEA, though the estimated effect size is small and insignificant. Column 2 reports results controlling for the respondent's own PSEA, as well as dummies for birth year to control for cohort effects, and dummies for birth month to control for seasonal effects. The effect size of birth order is not much changed.

Column 3 reports results controlling for parents' age at birth. Within a family, later children have older parents by definition. Older parents have more life experience and may have higher income, which may help later children. Kantarevic and Mechoulam (2006) show that mother's age at child-birth indeed mechanically offsets the negative effect of birth order. Including parents' age means we can separate the effect of parental age from birth order.¹⁵ This reduces the N by a lot, since only respondents with a live parent reported the necessary data. However, the effect of birth order jumps in size and becomes significant at the 5 per cent level. Meanwhile, parents' age has a positive effect. This suggests that estimates in columns 1-2 mixed two opposite-signed effects: having older parents versus being later in birth order.

Having tested that birth order affects spouse's PSEA, we now look for potential mediators of this effect. Despite the lower N, we continue to control for respondents' parents' age, since this removes a confound which would bias our results towards zero.¹⁶

Table 3 shows the results. Column 1 shows the effect of birth order, using the same specification as column 3 of the previous table. The remaining columns add potential mediators of birth order effects. Column 2 controls for our first measure of socio-economic status: university attendance. We also include potential non-SES mediators, which are affected by birth order and might affect spouse matching: fluid IQ, height, BMI and self-reported health. Column 3 adds our second measure of socio-economic status, income in first job. Column 4 includes both.

When we add university attendance and other mediators (column 2), the effect of birth order drops and becomes insignificant at 5%, while the coefficient for university is positive and highly significant. Fluid IQ, height and BMI are also positive and significant, while self-reported health has the right sign but is insignificant. Controlling for income instead of university attendance (column 3), again the effect of birth order shrinks and becomes insignificant, while income has a positive and highly significant effect. Lastly, the same pattern holds when we control for both university and income (column 4).

Under the assumptions discussed above, we can estimate the proportion of the birth order effect

¹⁵A possible critique is that later siblings by definition have older parents, so the parental age control is inappropriate. This may be true if we are estimating overall inequality between siblings. But here we are interested in using birth order as a shock, so it's reasonable to separate out its effects from those of parental age. The resulting estimate gives the counterfactual impact of having one more elder sibling, holding the age of one's parents constant.

¹⁶Table 13 in the appendix reports results without controlling for parents' age.

that is mediated by these variables. Table 4 reports this for each model in columns 2-4. Each estimate is the coefficient of birth order on the mediator, times the coefficient of the mediator on spouse PSEA, divided by the coefficient of birth order on spouse PSEA estimated from column 1, i.e. without mediators. Education explains about 38-55 percent of the effect, much more than all the other mediators. Income, fluid IQ, height and BMI all explain between 6 and 17 percent of the effect, depending on the specification.

These results provide evidence that birth order affects spouse PSEA via education and income, with education being especially important. The effect size of birth order is small (a few percent of a standard deviation of PSEA), but what matters is the effect size of education and income. The effect of education in particular is quite large as measured here, and since it also appears to mediate the purely environmental shock of birth order, it cannot just be due to an unobserved correlation with own genetics. This significant effect provides support for the central assumption in our model that $1 - a$ is non-zero and the marriage market significantly weighs SES.

Our next regressions split up the data into subsets. Cultural stereotypes often assume that the link between status and genes is not symmetric across the genders, for example, that males with high SES are particularly likely to marry attractive spouses. Claim 3 in the appendix shows that these differences would strengthen the effects of SGAM. To test for this, we separately regress female spouses' PSEA on male birth order, and male spouses' PSEA on female birth order. We also rerun regressions among the subset of individuals who had children. A significant result here will confirm that the association between status and genetics is carried over into the next generation.

Table 5 shows the results. Columns 1 and 2 present results using birth order of male respondents to predict female spouses' PSEA. Column 1 shows the regression of birth order plus controls; in column 2, we add university attendance and non-SES mediators (here, we exclude first job income so as to keep our N large). Columns 3 and 4 repeat the exercise for female respondents, using their birth order to predict male spouses' PSEA. The effect of birth order is imprecisely estimated in these subsets due to the lower sample size. However, the pattern of coefficient sizes is the same as in the main regression: the coefficient of birth order is about -0.3 (and very similar between the sexes), and adding university attendance reduces the absolute size of the birth order effect. Columns 5 and 6 show results from regressions on the subsample of couples with children. Here, birth order is significant in the base specification, and again, university attendance still seems to mediate the birth order effect.

Table 1: Regressions of mediators on birth order (Great Britain)

Estimates from OLS regressions corresponding to columns 1 and 2 in Table 3, separately for males, females and respondents with children. Spouse PSEA is the dependent variable, and own birth order and university attendance are the main independent variables. PSEA is the polygenic score for educational attainment, which is normalized with mean 0 and standard deviation 1. We include own PSEA, parents' age at birth (the mean of parent's ages) and further controls (family size, birth year, and birth month dummies) to ensure the balance of covariates across birth order. All data is from the UK Biobank for a sample of UK individuals born between 1935 and 1970. *** $p < 0.001$; ** $p < 0.01$; * $p < 0.05$; + $p < 0.1$. Standard errors clustered by spouse pair in parentheses.

Results: Norway

Now we turn to the results from MoBa in Norway. Some of the variables are different from those for UK Biobank. Spouse PSEA is calculated using summary statistics from Okbay et al. (2022), aka “EA4”, rather than “EA3”.¹⁷ Income is from all sources, reported at age 30, converted to a z score among respondents with the same gender, year of birth and year of reported income. In particular, some low-income individuals may be in continuing education or in relationships already.¹⁸ Data on IQ and self-reported health is unavailable. The sample is also younger than UK Biobank, spouse pairs are given rather than constructed, and all couples have at least one child.

Tables 6 and 7 are the equivalent of Tables 3 and 4 for respondents in the MoBa dataset. (Equivalents to Tables 1 and 2 are in the appendix.) The broad pattern of results is similar to Britain. The larger N gives higher statistical significance. Effects of all the variables are in the expected direction, except that the coefficient on income changes sign when university is also included. In particular, the point estimate of the total effect of birth order is about twice as high as in Britain, and the estimated effect of university attendance is also higher. The effect of own PSEA is also about twice as high. Note that these differences could be driven by the PSEA score containing less noise in the Norwegian sample.

Adding university attendance again substantially and significantly reduces the effect of birth order, though here, birth order remains independently significant and substantively large even controlling for university. In Norway, however, it is much less clear that income is an important mediator on its own. Adding income barely changes the effect of birth order (column 3). Table 7 computes the percentages of the effects that are mediated by our variables. The percentage effects of education, when controlling for income, are about the same in both countries. But the effect of income in the Norwegian sample is much smaller and very close to zero.

Table 8 runs our regressions separately for males and females.¹⁹ As in Britain, coefficients look very similar across the sexes. The effects of birth order are highly significant in either sex, and adding the mediators significantly reduces them. Interestingly, the effect of women’s BMI on their spouses’ PSEA is about 50% larger than the effect of men’s BMI, as in Britain, and here the difference is significant. On the other hand, in Norway, there is no difference between the male and female coefficients on university attendance.

¹⁷The R^2 on own university attendance is 0.0814 for EA4 in MoBa, compared to 0.04 for EA3 in UK Biobank.

¹⁸We also tried income at age 25. This gave odd results, with a significant negative beta on spouse PSEA. A possible reason is that in Norway many potential high earners are still in higher education at age 25. Income at age 25 correlated only at 0.1 with income at age 30, and was negatively correlated with educational attainment. Overall, we think income at 30 is more informative as a measure of SES.

¹⁹We don’t run separate regressions for families with children, since MoBa only includes families with children by design.

Overall, the Norway results show two things. First, they clearly confirm that birth order affects spouse PSEA, with education a key mediator. Second, they suggest that the effects of SES in marriage markets vary between the two countries. Education has a similar effect on spouse PSEA in Norway, but income has a much smaller effect. Of course this is a loose comparison, since even conditioning on our controls, samples and measures in the two countries are different. Still, it is interesting that in Norway, a more egalitarian country than the UK, income seems to have a smaller effect on spouse PSEA, while own PSEA, a genetic characteristic, seems to have a larger effect. This suggests that genetic and SES contributions to attractiveness (parameter α in our attractiveness equation) may vary between countries, and perhaps be endogenous to economic institutions.

Estimates from OLS regressions corresponding to columns 1 and 2 in Table 6, separately for males and females. Spouse PSEA is the dependent variable, and own birth order and university attendance are the main independent variables. PSEA is the polygenic score for educational attainment, which is normalized with mean 0 and standard deviation 1. We include own PSEA, parents' age at birth (the mean of parent's ages) and further controls (family size, birth year, and birth month dummies) to ensure the balance of covariates across birth order. All data is from the MoBa dataset for a sample of spouse pairs with a child between 1999 and 2008. *** $p < 0.001$; ** $p < 0.01$; * $p < 0.05$; + $p < 0.1$. Standard errors clustered by spouse pair in parentheses.

Robustness

As noted earlier, our results could conceivably be explained by spouses *only* mating on SES ($a = 0$ in our model), but with a pre-existing correlation between SES and PSEA in the population. That said, existing work strongly suggests that own PSEA affects spouse’s education (Robinson et al. 2017; Torvik et al. 2022). To confirm this we use a sample of siblings from the MoBa data²⁰, and regress spouse’s university attendance and income z-score on own PSEA, including sibling group fixed effects. Again, this uses the lottery of meiosis to guarantee that between-sibling differences in PSEA are exogenous to environmental characteristics including SES. Table 9 shows that own PSEA significantly increases the probability of spouse university attendance, by about 5% per standard deviation; interestingly, its effect on spouse income is insignificant and tightly bounded around zero, supporting the hypothesis that income is not an important form of SES in Norwegian marriage markets. By leveraging random PSEA variation between siblings, these results allow us to reject that $a = 0$ (even if the effect of PSEA on spouse SES could be *mediated* by own SES, cf. the extended model of meritocracy in appendix equation 5).

Table 9: Within-siblings regressions of spouse university attendance and income on own PSEA (Norway)

	University	Income
Own PSEA	0.0481 *** (0.0098)	−0.0012 (0.0174)
Sibling group dummies	Yes	Yes
Birth month dummies	Yes	Yes
Birth year dummies	Yes	Yes
N	9733	9759
Adj. R^2	0.182	0.084

Estimates from within-sibling-group regressions. PSEA is the polygenic score for educational attainment, which is normalized with mean 0 and standard deviation 1. Sibling group dummies are included to ensure exogeneity of PSEA. *** $p < 0.001$; ** $p < 0.01$; * $p < 0.05$; + $p < 0.1$. Standard errors in parentheses.

Although all children of the same parents have the same polygenic scores in expectation, it might

²⁰The UK Biobank sample has too few siblings with spouses for this analysis to be informative.

still be possible that genetics correlates with birth order within the sample. This could happen in three ways. First, siblings with high birth order will typically come from larger families than those with low birth order, and parents of different-sized families are likely to differ systematically on many dimensions, including genetics. We controlled for this by including a full set of family size dummies in the regression. Second, there could be selection bias. For example, if later siblings with high PSEA, and earlier siblings with low PSEA, are more likely to enter the sample, then this would bias our results. Thirdly, parents might choose family size in a way related to genetics. For example, suppose that when the first child has a phenotype reflecting a high PSEA, parents are more likely to have a second child. Then within the subset of two-child families, first children would have higher-than-average PSEA, while second children would not.

To check for the latter two problems, we run balance tests on 33 different polygenic scores in the UK Biobank sample.²¹ We regress each score on own birth order, controlling for family size.

Four scores were significant at $p < 0.10$, all with effect sizes of less than 0.02 per standard deviation. Table 19 in the appendix reports regressions controlling for these scores. Results are almost unchanged. To test whether polygenic scores might vary across birth orders within a particular family size, we also regress each score on a full set of birth order dummies, interacted with a full set of family size dummies. Of the 495 birth order coefficients, 20 were significant at $p < 0.05$; none were significant at $p < 0.001$. Among families of size 3, there is a marginally significant positive correlation of birth order with own PSEA (effect size 0.0277, $p = 0.06$). Table 22 in the appendix therefore reports regressions with families of size 3 excluded. Results are substantially unchanged. Of course, there could still be unmeasured genetic variants which correlate with birth order in our sample. Nevertheless, a wide set of polygenic scores shows no large or significant correlation. This makes us more confident that birth order is indeed exogenous to genetics (as Isungset et al. (2022) also find).

Another concern is that our chosen SES mediators might not be exogenous. We have already seen that birth order affects intelligence, height, BMI and health. So there might be other unobserved variables which mediate the effect of birth order on spousal PSEA, and which correlate with education or income, but which do not themselves capture SES. If so, that would threaten our claim that education and income are important mediators. However, the effects of education on spouse PSEA in Table 3, and of birth order on education in Table 1, are both large and highly significant. In other

²¹Polygenic scores were residualized on the first 100 principal components of the genetic data. Scores were for: ADHD, age at menarche, age at menopause, agreeableness, age at smoking initiation, alcohol use, Alzheimer's, autism, bipolarity, BMI, body fat, caffeine consumption, cannabis (ever vs. never), cognitive ability, conscientiousness, coronary artery disease, smoking (cigarettes per day), type II diabetes, drinks per week, educational attainment (EA2 and EA3), anorexia, extraversion, height, hip circumference, major depressive disorder, neuroticism, openness, smoking cessation, schizophrenia, smoking initiation, waist circumference, and waist-to-hip ratio. For full details of score construction, see Abdellaoui et al. (2019). We also ran similar tests on MoBa data, and found no significant associations between birth order and polygenic scores.

literature on spouse matching, education is a common, robust and significant predictor. For these reasons, we think that our results are unlikely to be driven wholly by other, unobserved mediators. In the appendix we run Oster (2019) style robustness checks where we formally ask how strong selection on unobservables would need to be to reduce the effect of our key mediators to zero.

A final concern is that polygenic scores, including PSEA, contain noise from correlated environments. (That is, effect sizes of individual SNPs may be confounded in the underlying statistical analyses used to create polygenic scores.) It is conceivable that birth order could only affect the noise component of spouse PSEA, rather than the component which is truly causal for education. We think this is unlikely for several reasons. First, our polygenic scores were calculated using per-SNP summary statistics estimated on non-UK populations. So they will only include noise that correlates with social environment insofar as non-causal correlations of SNPs with social status are the same across different countries. Second, true causal effects of individual SNPs are highly correlated ($r = 0.74$) with their “population effects” including noise (Young et al. 2022). Third, it is hard to imagine an assortative mating process by which people match spouses who have genetic variants that correlate with educational attainment, but not genetic variants that cause it. Lastly, our within-sibling regressions from Norway (Table 9) show that own PSEA is truly causal for spouse education; it is unlikely that the set of variants underlying this causality does not overlap with the variants causing own education.

Our main specification is linear in birth order. Tables 16 and 17 in the appendix run specifications with separate dummies for each birth order. The pattern that birth order coefficients shrink after controlling for SES mediators holds robustly across all birth orders in both Britain and Norway.

UK Biobank is not a representative sample of the population. Table 18 in the appendix weights cases to match the Biobank’s sampling frame. Results are similar to those in the main text. Although this is still not representative of the population as a whole, it provides some assurance that our results are not driven by volunteering bias.

As well as affecting spouse characteristics, birth order and own PSEA might affect whether people marry at all. Though this would not invalidate our results about married couples, we check for it. In fact, after controlling for parental age, there is little evidence that either birth order or PSEA affect one’s probability of having a partner (Table 23 in the appendix).

The appendix reports other robustness checks, including replacing university attendance with age of leaving full-time education. Overall, while significance sometimes varies, the pattern of results is remarkably consistent. Birth order is always negatively associated with spouse PSEA, and this effect is always reduced in magnitude after adding education as a mediator. Effect sizes are also consistent, with the exception that they are smaller if we do not control for parental age (just as in Table 2).

Conclusion

Our empirical analysis shows that in Great Britain and Norway, two contemporary developed countries, earlier-born siblings had spouses with higher PSEA. We also provide evidence that these effects are mediated by socio-economic status, specifically income and education. We interpret this as evidence of social-genetic assortative mating (SGAM).

Advantage is transmitted across generations by many mechanisms. Rich parents may invest more in their children's human capital, transfer wealth via gifts and bequests, model valuable skills, or provide them with advantageous social networks. They may also pass on causally relevant genetic variants. This channel has been proposed as a reason for the surprising persistence of inequality over generations (Clark and Cummins 2015; Clark 2023). One problem with this theory is that in the absence of assortative mating, genetic variation regresses swiftly to the mean, with coefficient $r = 0.5$ per generation. Thus to explain long-run persistence, the genetic theory seems to require very high levels of genetic assortative mating. SGAM may help to solve this puzzle. Persistence will be increased if, in addition to genetic assortative mating, high SES itself attracts "good genes". At the same time, SGAM changes the interpretation of genetics. Genetic variation is not an exogenous input into the social system, but an endogenous outcome. Policy changes redistributing SES will also, over generations, change the distribution of genetics in the population.

SGAM also provides a new explanation for genes-SES gradients – observed associations of genes with SES – which is an important cause of educational and occupational inequality, and perhaps also of health inequalities. The leading alternative explanation is meritocratic social mobility. Whilst meritocracy exists in modern capitalist economies, it has been far more limited in most societies throughout history (Smelser and Lipset 1966). On the other hand, assortative mating is likely to be a cultural universal (Buss 1989). Thus, SGAM predicts that genes-SES gradients should exist in all stratified societies. In fact, people in many societies have believed that innate traits do vary by social status.²² It may be possible to directly test for genetic differences across social status in ancient DNA samples.

Under SGAM, the association between SES and genetic variation depends on economic and social institutions. Institutions that make wealth more persistent across generations also increase the correlation between SES and genetics. If so, then institutional differences may have long-run effects over generations by altering the genes-SES gradient. There could be hysteresis, with initial social differences cumulating over time via their effect on genetic inequality. On the other hand, while lowering the intergenerational transmission of wealth may eventually flatten the genes-SES gradient, increases in the level of meritocracy paradoxically make it steeper, suggesting a deep con-

²²The appendix has a selection of relevant historical quotations.

flict between meritocracy and egalitarianism (Young 1958; Markovits 2019). Lastly, the structure of marriage markets also affects the gradient. Our empirical analysis suggests that in relatively egalitarian Norway, income plays a less important role in assortative mating than it does in the UK. However, this is a loose comparison, and we see careful tests of comparative statics across different contexts as an important challenge for future work.

The broadest message of this paper is that genetics are a social outcome. Both popular and scientific discourse often parse genetics as “nature”, in opposition to “nurture” or “environment” (e.g. Chakravarti and Little 2003; Plomin 2019). This reflects the fact that our individual genetic endowment is fixed at birth, affects our body and brain through proximate biological mechanisms, and cannot be changed by our social environment. But the idea that human genetics are natural can be highly misleading. Humans inherit their genes from their parents, along with other forms of inheritance such as economic and cultural capital. Human parents, in turn, form spouse pairs and bear children within social institutions. A person’s genetic inheritance is a social and historical fact about them, not just a fact of nature. As Marx (1844) wrote, “History is the true natural history of man”.

The theory of evolution suggests that two motivations are likely to be central for fitness-maximizing organisms: acquiring material resources so as to survive and raise offspring, and pursuing reproductive partners who themselves have high fitness value. Arguably, these two motives structure nearly all of human society. On this view, the genetics-SES trade in marriage markets is the most basic trade there is. Genetic endowments can be thought of as another form of capital, alongside human, social and cultural capital: a resource to be sought, accumulated and competed over. The analysis of this kind of capital is an exciting area for further research.

The Norwegian Mother, Father and Child Cohort Study (MoBa) is a population-based pregnancy cohort study conducted by the Norwegian Institute of Public Health. Participants were recruited from all over Norway from 1999-2008. The women consented to participation in 41% of the pregnancies. The cohort includes approximately 114,500 children, 95,200 mothers and 75,200 fathers. The current study is based on version 12 of the quality-assured data files released for research in 2019. The establishment of MoBa and initial data collection was based on a license from the Norwegian Data Protection Agency and approval from The Regional Committees for Medical and Health Research Ethics. The MoBa cohort is currently regulated by the Norwegian Health Registry Act. The current study was approved by The Regional Committees for Medical and Health Research Ethics (project # 2017/2205).

We thank the Norwegian Institute of Public Health (NIPH) for generating high-quality genomic data. This research is part of the HARVEST collaboration, supported by the Research Council of Norway (#229624). Proofs

We use random matching as a benchmark to compare against SGAM. Under random matching, the distribution of couples' characteristics is normal with mean 0 and covariance matrix

$$\mathbb{C} \begin{pmatrix} x_1 \\ x_2 \\ y_1 \\ y_2 \end{pmatrix} = \begin{pmatrix} s^2 & \sigma & 0 & 0 \\ \sigma & S^2 & 0 & 0 \\ 0 & 0 & s^2 & \sigma \\ 0 & 0 & \sigma & S^2 \end{pmatrix}.$$

Proof of Proposition 1. By a change of variable, rewrite:

$$\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \rightarrow \begin{pmatrix} x_1 \\ u \end{pmatrix} \text{ where } u = \frac{ax_1 + (1-a)x_2}{\sqrt{a^2s^2 + (1-a)^2S^2 + 2a(1-a)\sigma}} = \frac{ax_1 + (1-a)x_2}{\sigma_I}$$

is the attractiveness rescaled to $\mathcal{N}(0, 1)$. Thus,

$$\begin{pmatrix} x_1 \\ u \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ a/\sigma_I & (1-a)/\sigma_I \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix}.$$

Note that the means are still zero, but the covariance of (x_1, u) is:

$$\begin{aligned} \mathbb{C} \begin{pmatrix} x_1 \\ u \end{pmatrix} &= \begin{pmatrix} 1 & 0 \\ a/\sigma_I & (1-a)/\sigma_I \end{pmatrix} \begin{pmatrix} s^2 & \sigma \\ \sigma & S^2 \end{pmatrix} \begin{pmatrix} 1 & a/\sigma_I \\ 0 & (1-a)/\sigma_I \end{pmatrix} \\ &= \begin{pmatrix} s^2 & A \\ A & 1 \end{pmatrix} \end{aligned}$$

where

$$A = \frac{as^2 + (1-a)\sigma}{\sqrt{a^2s^2 + (1-a)^2S^2 + 2a(1-a)\sigma}} = \frac{as^2 + (1-a)\sigma}{\sigma_I}.$$

Under SGAM, individual $\begin{pmatrix} x_1 \\ u \end{pmatrix}$ is matched with $\begin{pmatrix} y_1 \\ v \end{pmatrix}$ such that $u = v = t$.

The distribution of t is $\mathcal{N}(0, 1)$. Therefore the vector $\begin{pmatrix} x_1 \\ y_1 \\ t \end{pmatrix}$ is normally distributed, with mean

0, and covariance

$$\Sigma = \begin{pmatrix} s^2 & A^2 & A \\ A^2 & s^2 & A \\ A & A & 1 \end{pmatrix}$$

Finally, we are interested in

$$\begin{pmatrix} x_1 \\ x_2 \\ y_1 \\ y_2 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ -\frac{a}{1-a} & 0 & \frac{\sigma_I}{1-a} \\ 0 & 1 & 0 \\ 0 & -\frac{a}{1-a} & \frac{\sigma_I}{1-a} \end{pmatrix} \begin{pmatrix} x_1 \\ y_1 \\ t \end{pmatrix}$$

therefore again the means are 0 and

$$\begin{aligned} \mathbb{C} \begin{pmatrix} x_1 \\ x_2 \\ y_1 \\ y_2 \end{pmatrix} &= \begin{pmatrix} 1 & 0 & 0 \\ -\frac{a}{1-a} & 0 & \frac{\sigma_I}{1-a} \\ 0 & 1 & 0 \\ 0 & -\frac{a}{1-a} & \frac{\sigma_I}{1-a} \end{pmatrix} \Sigma \begin{pmatrix} 1 & 0 & 0 \\ -\frac{a}{1-a} & 0 & \frac{\sigma_I}{1-a} \\ 0 & 1 & 0 \\ 0 & -\frac{a}{1-a} & \frac{\sigma_I}{1-a} \end{pmatrix}^T \\ &= \begin{pmatrix} s^2 & \sigma & A^2 & AC \\ \sigma & S^2 & AC & C^2 \\ A^2 & AC & s^2 & \sigma \\ AC & C^2 & \sigma & S^2 \end{pmatrix} \end{aligned}$$

where:

$$\begin{aligned} A &= \frac{as^2 + (1-a)\sigma}{\sigma_I} \text{ and} \\ C &= \frac{a\sigma + (1-a)S^2}{\sigma_I}. \end{aligned}$$

□

Lemma 1. $C^2 \leq S^2$, with strict inequality if $a > 0$ and $\sigma < 1$.

Proof. Write

$$\begin{aligned}
C^2 &= \frac{a^2\sigma^2 + (1-a)^2S^4 + 2a(1-a)\sigma S^2}{a^2s^2 + (1-a)^2S^2 + 2a(1-a)\sigma} \\
&\leq \frac{a^2s^2S^2 + (1-a)^2S^4 + 2a(1-a)\sigma S^2}{a^2s^2 + (1-a)^2S^2 + 2a(1-a)\sigma}, \text{ since } \sigma/sS = \text{Corr}(x_1, x_2) \leq 1 \\
&= S^2
\end{aligned}$$

and observe that the inequality is strict if $a > 0$ and $\sigma < sS$. $\square$

Proof of Claim 1. From (3), the joint distribution of $(\frac{\tau}{2}(x_1 + y_1) + \varepsilon, x_2, y_2)$ is normal with mean $(0, 0, 0)$ and covariance

$$\Sigma = \begin{pmatrix} \frac{1}{2}\tau^2(A^2 + s^2) + 1 & \frac{\tau}{2}(\sigma + AC) & \frac{\tau}{2}(\sigma + AC) \\ \frac{\tau}{2}(\sigma + AC) & S^2 & C^2 \\ \frac{\tau}{2}(\sigma + AC) & C^2 & S^2 \end{pmatrix}$$

Using the matrix formula for the conditional mean of normal variables,

$$\begin{aligned}
\mathbb{E} \left[\frac{\tau}{2}(x_1 + y_1) + \varepsilon \mid x_2 = v, y_2 = w \right] &= \begin{pmatrix} \frac{\tau}{2}(\sigma + AC) & \frac{\tau}{2}(\sigma + AC) \end{pmatrix} \begin{pmatrix} S^2 & C^2 \\ C^2 & S^2 \end{pmatrix}^{-1} \begin{pmatrix} v \\ w \end{pmatrix} \\
&= \frac{1}{2}\tau \frac{\sigma + AC}{C^2 + S^2} (v + w) \tag{12}
\end{aligned}$$

In particular, if $\sigma = 0$, we have

$$\begin{aligned}
A &= \frac{as^2}{\sqrt{a^2s^2 + (1-a)^2S^2}} \text{ and} \\
C &= \frac{(1-a)S^2}{\sqrt{a^2s^2 + (1-a)^2S^2}},
\end{aligned}$$

and (12) becomes

$$\begin{aligned}
\mathbb{E} \left[\frac{\tau}{2}(x_1 + y_1) + \varepsilon \mid x_2 = v, y_2 = w \right] &= \frac{1}{2}\tau \frac{a(1-a)s^2}{a^2s^2 + 2(1-a)^2S^2} (v + w) \\
&= \frac{1}{2}\tau \frac{a(1-a)\lambda}{a^2\lambda + 2(1-a)^2} (v + w)
\end{aligned}$$

where $\lambda = s^2/S^2$ is the ratio of genetic variance to wealth variance. The coefficient $\frac{a(1-a)\lambda}{a^2\lambda+2(1-a)^2}$ is increasing, then decreasing in a and is 0 for $a = 0$ or $a = 1$. $\square$

Proof of Claim 2. Again applying (3), under SGAM, the correlation between children's traits is:

$$\text{Corr}(x'_1, x'_2) = \frac{\frac{1}{2}\theta\tau(\sigma + AC)}{\sqrt{\frac{1}{2}\tau^2(A^2 + s^2) + 1}\sqrt{\frac{1}{2}\theta^2(C^2 + S^2) + 1}}$$

This is positive if $\sigma = 0$ so long as $AC > 0$ i.e. $0 < a < 1$. To show it is increasing in θ , strip out constant terms and take the derivative of

$$\frac{\theta}{\sqrt{\frac{1}{2}\theta^2(C^2 + S^2) + 1}}$$

The derivative is signed by

$$\begin{aligned} & \left(\frac{1}{2}\theta^2(C^2 + S^2) + 1\right)^{0.5} - \frac{1}{2}\theta^2(C^2 + S^2) \left(\frac{1}{2}\theta^2(C^2 + S^2) + 1\right)^{-0.5} \\ & > \left(\frac{1}{2}\theta^2(C^2 + S^2) + 1\right)^{0.5} - \left(\frac{1}{2}\theta^2(C^2 + S^2) + 1\right) \left(\frac{1}{2}\theta^2(C^2 + S^2) + 1\right)^{-0.5} \\ & = 0. \end{aligned}$$

$\square$

Proof of Proposition 2. We drop the bars over $\bar{s}$, $\bar{S}$ and $\bar{\sigma}$ for the proof, since we won't need to refer to the initial values. Start by characterizing the invariant distribution. This must satisfy:

$$\begin{pmatrix} s^2 & \sigma \\ \sigma & S^2 \end{pmatrix} = \begin{pmatrix} \frac{1}{2}\tau^2(A^2 + s^2) + 1 & \frac{1}{2}\theta\tau(\sigma + AC) \\ \frac{1}{2}\theta\tau(\sigma + AC) & \frac{1}{2}\theta^2(C^2 + S^2) + 1 \end{pmatrix}$$

where

$$\begin{aligned} A &= \frac{as^2 + (1-a)\sigma}{\sqrt{a^2s^2 + (1-a)^2S^2 + 2a(1-a)\sigma}} \text{ and} \\ C &= \frac{a\sigma + (1-a)S^2}{\sqrt{a^2s^2 + (1-a)^2S^2 + 2a(1-a)\sigma}}, \end{aligned}$$

Note that if the distribution converges, s^2 and S^2 must be above 1. Also, for A and C to have a

real-valued solution, it must be that $a^2 s^2 + (1-a)^2 S^2 + 2a(1-a)\sigma > 0$; using this,

$$AC = \frac{a^2 s^2 \sigma + (1-a)^2 S^2 \sigma + a(1-a)(\sigma^2 + S^2 s^2)}{a^2 s^2 + (1-a)^2 S^2 + 2a(1-a)\sigma} > \sigma, \text{ by } \sigma^2 < S^2 s^2.$$

Since $AC > \sigma$, $\frac{\theta\tau}{2}(\sigma + AC) > \theta\tau\sigma$. If $\sigma < 0$ then $\sigma = \frac{\theta\tau}{2}(\sigma + AC) > \theta\tau\sigma > \sigma$, a contradiction. Thus $\sigma \geq 0$. Also if $\sigma = 0$ then

$$\sigma = \frac{\theta\tau}{2} \left(\frac{a(1-a)(S^2 s^2)}{a^2 s^2 + (1-a)^2 S^2} \right)$$

which implies $a = 0$ or $a = 1$. This proves that σ is non-negative, and positive if $a \in (0, 1)$, so long as the distribution converges.

From the invariant distribution, first:

$$\sigma \left(1 - \frac{1}{2}\theta\tau \right) = \frac{\theta\tau}{2} \frac{(a s^2 + (1-a)\sigma)(a\sigma + (1-a)S^2)}{a^2 s^2 + (1-a)^2 S^2 + 2a(1-a)\sigma}$$

or

$$\mu \left(1 - \frac{1}{2}\theta\tau \right) = \frac{\theta\tau}{2} \frac{(a\lambda + (1-a)\mu)(a\mu + (1-a))}{a^2 \lambda + (1-a)^2 + 2a(1-a)\mu}$$

where

$$\lambda = s^2/S^2 \text{ and } \mu = \sigma/S^2.$$

Solving for λ gives

$$\lambda = \frac{1-a}{a} \mu \frac{(-2a + 4a\mu - 2\theta\tau + 2a\theta\tau - 3a\theta\tau\mu + 2)}{(1-a)\theta\tau - 2a\mu(1-\theta\tau)} \quad (13)$$

Then

$$\begin{aligned} s^2 \left(1 - \frac{1}{2}\tau^2 \right) &= \frac{1}{2} A^2 \tau^2 + 1 \\ S^2 \left(1 - \frac{1}{2}\theta^2 \right) &= \frac{1}{2} C^2 \theta^2 + 1 \end{aligned}$$

give

$$\begin{aligned} s^2 \left(1 - \frac{1}{2}\tau^2 \right) - \frac{1}{2} A^2 \tau^2 &= S^2 \left(1 - \frac{1}{2}\theta^2 \right) - \frac{1}{2} C^2 \theta^2, \text{ therefore} \\ \lambda \left(1 - \frac{1}{2}\tau^2 \right) - \frac{1}{2} \frac{A^2}{S^2} \tau^2 &= \left(1 - \frac{1}{2}\theta^2 \right) - \frac{1}{2} \frac{C^2}{S^2} \theta^2 \end{aligned}$$

Here

$$\begin{aligned}\frac{A^2}{S^2} &= \frac{(a\lambda + (1-a)\mu)^2}{D} \quad \text{and} \\ \frac{C^2}{S^2} &= \frac{(a\mu + (1-a))^2}{D}, \\ D &= a^2\lambda + (1-a)^2 + 2a(1-a)\mu\end{aligned}$$

which give a quadratic equation in μ :

$$\lambda \left(1 - \frac{1}{2}\tau^2\right) D - \frac{1}{2}(a\lambda + (1-a)\mu)^2 \tau^2 - \left(1 - \frac{1}{2}\theta^2\right) D + \frac{1}{2}(a\mu + (1-a))^2 \theta^2 = 0$$

Plugging in λ given by (13), this can be rewritten to

$$F(\mu) = \frac{(1-a+a\mu)^2}{a} \frac{N(\mu)}{D(\mu)} = 0$$

where

$$N(\mu) = X\mu^2 + Y\mu + Z, \quad \text{with } X, Y, Z \text{ polynomials in } a, \theta, \tau$$

and

$$D(\mu) = (\theta\tau(1-a) - 2a\mu(1-\theta\tau))^2$$

One can check that the discriminant is always positive. Therefore this has two solutions (not shown), of which only one is acceptable (it goes to the exact solution when the coefficient of μ^2 goes to 0). Writing

$$\mu = \phi_1(a, \theta, \tau)$$

for this solution:

$$\lambda = \psi(a, \theta, \tau) = \frac{1-a}{a} \phi_1(a, \theta, \tau) \frac{(-2a + 4a\phi_1(a, \theta, \tau) - 2\theta\tau + 2a\theta\tau - 3a\theta\tau\phi_1(a, \theta, \tau) + 2)}{(1-a)\theta\tau - 2a\phi_1(a, \theta, \tau)(1-\theta\tau)}.$$

Finally

$$\begin{aligned}S^2 &= \frac{1}{1 - \frac{1}{2}\theta^2 - \frac{1}{2}\frac{C^2}{S^2}\theta^2} \quad \text{where} \\ \frac{C^2}{S^2} &= \frac{(a\phi_1(a, \theta, \tau) + (1-a))^2}{a^2\psi(a, \theta, \tau) + (1-a)^2 + 2a(1-a)\phi_1(a, \theta, \tau)}\end{aligned}$$

and

$$s^2 = \lambda S^2 = \frac{\psi(a, \theta, \tau)}{1 - \frac{1}{2}\theta^2 - \frac{1}{2}\frac{C^2}{S^2}\theta^2};$$

$$\sigma = \mu S^2 = \frac{\phi_1(a, \theta, \tau)}{1 - \frac{1}{2}\theta^2 - \frac{1}{2}\frac{C^2}{S^2}\theta^2}.$$

Conditional expectations of children's genetics given parents' wealth under SGAM are calculated using the same formula as before, plugging in moments of the asymptotic distribution:

$$\mathbb{E} \left[\frac{\tau}{2} (x_1 + y_1) + \varepsilon \mid x_2 = v, y_2 = w \right] = \frac{1}{2} \tau \frac{\sigma + AC}{C^2 + S^2} (v + w)$$

□

Extensions

Meritocracy

Proof of Proposition 3. Write

$$x'_1 = \tau \frac{x_1 + y_1}{2} + \varepsilon$$

$$x'_2 = \gamma x'_1 + \theta \frac{x_2 + y_2}{2} + \eta$$

$$= \gamma \tau \frac{x_1 + y_1}{2} + \theta \frac{x_2 + y_2}{2} + \eta + \gamma \varepsilon$$

Since

$$\begin{pmatrix} \tau \frac{x_1 + y_1}{2} \\ \gamma \tau \frac{x_1 + y_1}{2} + \theta \frac{x_2 + y_2}{2} \end{pmatrix} = \begin{pmatrix} \frac{\tau}{2} & 0 & \frac{\tau}{2} & 0 \\ \frac{\gamma\tau}{2} & \frac{\theta}{2} & \frac{\gamma\tau}{2} & \frac{\theta}{2} \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ y_1 \\ y_2 \end{pmatrix}$$

we can use (1) to derive the covariance matrix for children:

$$\begin{aligned}
\mathbb{C} &= \begin{pmatrix} 1 & \gamma \\ \gamma & 1 + \gamma^2 \end{pmatrix} + \begin{pmatrix} \frac{\tau}{2} & 0 & \frac{\tau}{2} & 0 \\ \frac{\gamma\tau}{2} & \frac{\theta}{2} & \frac{\gamma\tau}{2} & \frac{\theta}{2} \end{pmatrix} \begin{pmatrix} s^2 & \sigma & A^2 & AC \\ \sigma & S^2 & AC & C^2 \\ A^2 & AC & s^2 & \sigma \\ AC & C^2 & \sigma & S^2 \end{pmatrix} \begin{pmatrix} \frac{\tau}{2} & \frac{\gamma\tau}{2} \\ 0 & \frac{\theta}{2} \\ \frac{\tau}{2} & \frac{\gamma\tau}{2} \\ 0 & \frac{\theta}{2} \end{pmatrix} \\
&= \begin{pmatrix} \frac{\tau^2}{2}(s^2 + A^2) + 1 & \frac{\gamma\tau^2}{2}(s^2 + A^2) + \frac{\tau\theta}{2}(\sigma + AC) + \gamma \\ \frac{\gamma\tau^2}{2}(s^2 + A^2) + \frac{\tau\theta}{2}(\sigma + AC) + \gamma & \frac{\gamma^2\tau^2}{2}(s^2 + A^2) + \gamma\tau\theta(\sigma + AC) + \frac{\theta^2}{2}(S^2 + C^2) + 1 + \gamma^2 \end{pmatrix}
\end{aligned}$$

The first claim in the proof follows from the covariance:

$$\frac{\gamma\tau^2}{2}(s^2 + A^2) + \frac{\tau\theta}{2}(\sigma + AC) + \gamma$$

This is increasing in γ , and positive if any of $\sigma > 0$, $\gamma > 0$, or $AC > 0$ (which holds if $0 < a < 1$ when $\sigma = 0$).

The correlation $Cov(x'_1, x'_2)/\sqrt{Var(x'_1)Var(x'_2)}$ is proportional to

$$\frac{\gamma p + q}{\sqrt{\gamma^2 p + \gamma 2q + r}}$$

where

$$p = \tau^2(s^2 + A^2) + 2;$$

$$q = \tau\theta(\sigma + AC);$$

$$r = \theta^2(S^2 + C^2) + 2.$$

The derivative of this with respect to γ is signed by $pr - q^2$, which equals

$$\begin{aligned}
&[\tau^2(s^2 + A^2) + 2][\theta^2(S^2 + C^2) + 2] - [\tau\theta(\sigma + AC)]^2 \\
&= \tau^2\theta^2(s^2S^2 + A^2S^2 + s^2C^2 - 2\sigma AC - \sigma^2) + 2[\theta^2(S^2 + C^2) + \tau^2(s^2 + A^2)] + 4
\end{aligned}$$

The last two terms are positive. In the first term, $\sigma^2 < s^2 S^2$, and

$$\begin{aligned} 0 &< (AS - Cs)^2 \\ &= A^2 S^2 + C^2 s^2 - 2AC Ss \\ &< A^2 S^2 + C^2 s^2 - 2\sigma AC, \text{ again using } \sigma < sS. \end{aligned}$$

Hence the whole sum is positive.

Now we can calculate

$$\mathbb{E}[x'_2 | x_2 + y_2]$$

using

$$\begin{pmatrix} \gamma\tau \frac{x_1+y_1}{2} + \theta \frac{x_2+y_2}{2} \\ x_2 \\ y_2 \end{pmatrix} = \begin{pmatrix} \frac{\gamma\tau}{2} 0 & \frac{\theta}{2} 1 & \frac{\gamma\tau}{2} 0 & \frac{\theta}{2} 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \\ y_1 \\ y_2 \end{pmatrix}$$

to give

$$\begin{aligned} \mathbb{C} \begin{pmatrix} x'_2 \\ x_2 \\ y_2 \end{pmatrix} &= \begin{pmatrix} \frac{\gamma\tau}{2} & \frac{\theta}{2} & \frac{\gamma\tau}{2} & \frac{\theta}{2} \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} s^2 & \sigma & A^2 & AC \\ \sigma & S^2 & AC & C^2 \\ A^2 & AC & s^2 & \sigma \\ AC & C^2 & \sigma & S^2 \end{pmatrix} \begin{pmatrix} \frac{\gamma\tau}{2} & 0 & 0 \\ \frac{\theta}{2} & 1 & 0 \\ \frac{\gamma\tau}{2} & 0 & 0 \\ \frac{\theta}{2} & 0 & 1 \end{pmatrix} + \begin{pmatrix} 1 + \gamma^2 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \\ &= \begin{pmatrix} \dots & \frac{\gamma\tau}{2}(\sigma + AC) + \frac{\theta}{2}(S^2 + C^2) & \frac{\gamma\tau}{2}(\sigma + AC) + \frac{\theta}{2}(S^2 + C^2) \\ \frac{\gamma\tau}{2}(\sigma + AC) + \frac{\theta}{2}(S^2 + C^2) & S^2 & C^2 \\ \frac{\gamma\tau}{2}(\sigma + AC) + \frac{\theta}{2}(S^2 + C^2) & C^2 & S^2 \end{pmatrix}. \end{aligned}$$

Next

$$\begin{aligned} \mathbb{E}[x'_2 | x_2, y_2] &= \begin{pmatrix} \frac{\gamma\tau}{2}(\sigma + AC) + \frac{\theta}{2}(S^2 + C^2) & \frac{\gamma\tau}{2}(\sigma + AC) + \frac{\theta}{2}(S^2 + C^2) \end{pmatrix} \begin{pmatrix} S^2 & C^2 \\ C^2 & S^2 \end{pmatrix}^{-1} \begin{pmatrix} x_2 \\ y_2 \end{pmatrix} \\ &= \left(\gamma\tau \frac{\sigma + AC}{S^2 + C^2} + \theta \right) \frac{x_2 + y_2}{2} \end{aligned}$$

So long as $0 < a < 1$ or $\sigma > 0$, the coefficient on parents' wealth is thus higher than θ .

□

Different attractiveness weights for men and women

The relative attractiveness of genes and SES might differ for men and women. Our basic result extends to this setup.

Claim 3. *Suppose that men's and women's attractiveness is given by*

$$i(x) = ax_1 + (1 - a)x_2,$$

$$j(y) = by_1 + (1 - b)y_2$$

respectively, with $0 \leq a \leq 1, 0 \leq b \leq 1$. Then if $\sigma = 0$, children's characteristics x'_1 and x'_2 will be positively correlated unless $a = b = 0$ or $a = b = 1$. The correlation is increasing in θ .

Interestingly, the x_1 - x_2 correlation is highest when a and b are most different from each other. So gender differences in what counts as attractive make the effects of SGAM stronger. Intuitively, if one sex only assort on SES while the other sex only assort on genetics, this induces a very reliable correlation between genes and SES in couples, since (e.g.) every high-SES male is matched for sure with a high-genetics female.

Proof of Claim 3. Since men and women have different distributions of attractiveness, we have to match them by quantiles of their respective distributions. Men's and women's attractiveness are distributed

$$N(0, \sigma_I^2) \text{ where } \sigma_I = \sqrt{a^2 s^2 + (1 - a)^2 S^2 + 2a(1 - a)\sigma};$$

$$N(0, \sigma_J^2) \text{ where } \sigma_J = \sqrt{b^2 s^2 + (1 - b)^2 S^2 + 2b(1 - b)\sigma}.$$

Thus, men with normalized attractiveness $i(x)/\sigma_I$ match women with normalized attractiveness $j(y)/\sigma_J$.

Change variables so that

$$\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \rightarrow \begin{pmatrix} x_1 \\ u \end{pmatrix} \text{ where } u = \frac{ax_1 + (1 - a)x_2}{\sigma_I};$$

$$\begin{pmatrix} y_1 \\ y_2 \end{pmatrix} \rightarrow \begin{pmatrix} y_1 \\ v \end{pmatrix} \text{ where } v = \frac{by_1 + (1 - b)y_2}{\sigma_J}.$$

Thus

$$\begin{pmatrix} x_1 \\ u \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ a/\sigma_I & (1-a)/\sigma_I \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix};$$

$$\begin{pmatrix} y_1 \\ v \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ b/\sigma_J & (1-b)/\sigma_J \end{pmatrix} \begin{pmatrix} y_1 \\ y_2 \end{pmatrix}.$$

and their respective covariance matrices are

$$\begin{aligned} \mathbb{C} \begin{pmatrix} x_1 \\ u \end{pmatrix} &= \begin{pmatrix} 1 & 0 \\ a/\sigma_I & (1-a)/\sigma_I \end{pmatrix} \begin{pmatrix} s^2 & \sigma \\ \sigma & S^2 \end{pmatrix} \begin{pmatrix} 1 & a/\sigma_I \\ 0 & (1-a)/\sigma_I \end{pmatrix} \\ &= \begin{pmatrix} s^2 & A \\ A & 1 \end{pmatrix}, \text{ where } A = \frac{as^2 + (1-a)\sigma}{\sigma_I}; \end{aligned}$$

similarly

$$\mathbb{C} \begin{pmatrix} y_1 \\ v \end{pmatrix} = \begin{pmatrix} s^2 & B \\ B & 1 \end{pmatrix}, \text{ where } B = \frac{bs^2 + (1-b)\sigma}{\sigma_J}.$$

Under SGAM, couples have characteristics $\begin{pmatrix} x_1 \\ t \\ y_1 \\ t \end{pmatrix}$, where $\begin{pmatrix} x_1 \\ y_1 \\ t \end{pmatrix}$ is trivariate normal with mean 0 and covariance matrix

$$\Sigma = \begin{pmatrix} s^2 & AB & A \\ AB & s^2 & B \\ A & B & 1 \end{pmatrix}$$

Lastly, we calculate the covariance matrix of couples' original characteristics. Since

$$\begin{pmatrix} x_1 \\ x_2 \\ y_1 \\ y_2 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ \frac{-a}{1-a} & 0 & \frac{\sigma_I}{1-a} \\ 0 & 1 & 0 \\ 0 & \frac{-b}{1-b} & \frac{\sigma_J}{1-b} \end{pmatrix} \begin{pmatrix} x_1 \\ y_1 \\ t \end{pmatrix}$$

we have that the mean is again 0 and the covariance matrix is

$$\begin{aligned}\mathbb{C} \begin{pmatrix} x_1 \\ x_2 \\ y_1 \\ y_2 \end{pmatrix} &= \begin{pmatrix} 1 & 0 & 0 \\ \frac{-a}{1-a} & 0 & \frac{\sigma_I}{1-a} \\ 0 & 1 & 0 \\ 0 & \frac{-b}{1-b} & \frac{\sigma_J}{1-b} \end{pmatrix} \Sigma \begin{pmatrix} 1 & \frac{-a}{1-a} & 0 & 0 \\ 0 & 0 & 1 & \frac{-b}{1-b} \\ 0 & \frac{\sigma_I}{1-a} & 0 & \frac{\sigma_J}{1-b} \end{pmatrix} \\ &= \begin{pmatrix} s^2 & \sigma & AB & AD \\ \sigma & S^2 & BC & CD \\ AB & BC & s^2 & \sigma \\ AD & CD & \sigma & S^2 \end{pmatrix}\end{aligned}$$

where

$$C = \frac{a\sigma + (1-a)S^2}{\sigma_I}; D = \frac{b\sigma + (1-b)S^2}{\sigma_J}.$$

From the above and (2) we can calculate the covariance matrix of children's characteristics as

$$\begin{aligned}\mathbb{C} \begin{pmatrix} x'_1 \\ x'_2 \end{pmatrix} &= \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} + \begin{pmatrix} \frac{\tau}{2} & 0 & \frac{\tau}{2} & 0 \\ 0 & \frac{\theta}{2} & 0 & \frac{\theta}{2} \end{pmatrix} \begin{pmatrix} s^2 & \sigma & AB & AD \\ \sigma & S^2 & BC & CD \\ AB & BC & s^2 & \sigma \\ AD & CD & \sigma & S^2 \end{pmatrix} \begin{pmatrix} \frac{\tau}{2} & 0 \\ 0 & \frac{\theta}{2} \\ \frac{\tau}{2} & 0 \\ 0 & \frac{\theta}{2} \end{pmatrix} \\ &= \begin{pmatrix} \frac{\tau^2}{2}(s^2 + AB) + 1 & \frac{\tau\theta}{4}(2\sigma + AD + BC) \\ \frac{\tau\theta}{4}(2\sigma + AD + BC) & \frac{\theta^2}{2}(S^2 + CD) + 1 \end{pmatrix}.\end{aligned}$$

Thus x'_1 and x'_2 will be positively correlated if $2\sigma + AD + BC > 0$. This is always positive if $\sigma > 0$; if $\sigma = 0$ it reduces to

$$\frac{(a + b - 2ab)s^2 S^2}{\sigma_I \sigma_J}$$

which is positive unless $a = b = 0$ or $a = b = 1$. The correlation is

$$\frac{\frac{\tau\theta}{4}(2\sigma + AD + BC)}{\sqrt{\frac{\tau^2}{2}(s^2 + AB) + 1} \sqrt{\frac{\theta^2}{2}(S^2 + CD) + 1}}$$

and taking the derivative shows it is increasing in θ , as in the proof for Claim 2. $\square$

Non-linear attractiveness, non-normal x_1 and x_2 .

We consider non-normal distributions of x_1 and x_2 , non-normal shocks ε and η , and non-linear attractiveness functions. Suppose

$$i(x) = f(ax_1, (1-a)x_2) \quad (14)$$

with f strictly increasing in both its arguments. Our sole condition on the distribution of x is that not everybody with attractiveness i is both genetically and socially identical. In particular, this allows for discrete distributions, like some kinds of social status for x_2 , and monogenic or oligogenic attractiveness phenotypes for x_1 .

Proposition 4. *Let attractiveness be given by (14). Let (x_1, x_2) have any distribution such that a positive measure of the population has $i(x) = i$ where the conditional distribution of (x_1, x_2) given $i(x) = i$ is non-degenerate. Let η and ε be mean 0 and independent of x and each other. If genetics and SES are uncorrelated for the parents, then the correlation among children is non-negative, and strictly positive if $0 < a < 1$.*

Proof of Proposition 4. Without loss of generality let $Ex_1 = Ex_2 = 0$. The correlation is signed by the covariance. Write K for the set of couples in the parents' generation with typical member $k = (x, y)$. Without loss of generality let $x_1 \geq y_1$. Then, since the iso-attractiveness curves defined by f are downward-sloping, $x_2 \leq y_2$. (If $a = 1$ then $x_1 = y_1$; pick x so that $x_2 \leq y_2$.) Also, for $a \in (0, 1)$, if $x_1 > y_1$ then $x_2 < y_2$.

Since $Ex_1 = Ex_2 = 0$, the covariance among the parents' generation is

$$\int_K (x_1x_2 + y_1y_2)/2 \, dk$$

Write

$$\begin{aligned} x'_1 &= \tau x_1^* + \varepsilon & \text{where } x_1^* &= (x_1 + y_1)/2 \\ x'_2 &= \theta x_2^* + \eta & \text{where } x_2^* &= (x_2 + y_2)/2 \end{aligned}$$

and write the children's covariance as

$$Cov(x'_1, x'_2) = Cov(\tau x_1^*, \theta x_2^*) + Cov(\tau x_1^*, \eta) + Cov(\varepsilon, \theta x_2^*) + Cov(\varepsilon, \eta).$$

By independence of the shocks, the last 3 terms are zero. So we need to show that

$$Cov(\tau x_1^*, \theta x_2^*) = \tau \theta Cov(x_1^*, x_2^*) > 0$$

Write

$$Cov(x_1^*, x_2^*) = \int_K x_1^* x_2^* dk$$

using that $Ex_1^* = Ex_2^* = 0$.

Take a typical parent, and write

$$\begin{aligned} x_1 x_2 &= (x_1^* - \Delta_1)(x_2^* - \Delta_2) \\ y_1 y_2 &= (x_1^* + \Delta_1)(x_2^* + \Delta_2) \end{aligned}$$

where

$$\Delta_1 = (x_1 - y_1)/2; \Delta_2 = (x_2 - y_2)/2.$$

By assumption $\Delta_1 \geq 0$ and $\Delta_2 \leq 0$. Furthermore, if $a \in (0, 1)$, then for a set of positive measure, $\Delta_1 > 0$ and $\Delta_2 < 0$, by our assumption that not all matching couples are identical.

Taking the average of the parents gives

$$(x_1 x_2 + y_1 y_2)/2 = x_1^* x_2^* + \Delta_1 \Delta_2$$

and if $a \in (0, 1)$, this is strictly less than $x_1^* x_2^*$ for a set of positive measure. Plugging this into the integral gives

$$Cov(x_1, x_2) \leq Cov(x_1^*, x_2^*) = \int_K x_1^* x_2^* dk$$

with strict inequality if $a \in (0, 1)$. Since the parental covariance was 0 by assumption, this completes the proof.

□

More empirical results

Figure 5 redoes Figure 4 for the MoBa data, plotting measures of individual SES against spouse PSEA. While university attendance gives results similar to the UK, the relationship between income decile and spouse PSEA is interestingly nonlinear in both sexes. Some low-income individuals may be out of the labour market, either in continuing education or as a stay-at-home spouse.

Table 10 shows regressions of birth order on mediators for the MoBa data. Birth order predicts all the mediators significantly and with large effect sizes, except for BMI.

Table 11 regresses birth order on spouse PSEA for the MoBa data, starting with a simple bivariate regression and adding controls as in Table 2. Here, the negative effect of birth order is highly significant even before we control for parental age. As in Britain, the effect is greatly increased when we control for parental age.

Table 12 reruns Table 2, holding the sample fixed to ensure that sample selection does not drive the differences between columns. Despite the smaller samples, the basic pattern of results is the same as in the main text: birth order is only significant after controlling for parental age.

Table 13 reruns our central regressions in the UK, dropping the control for parents' age at birth. Results show the same pattern as in the main text: the coefficient for birth order is negative, but changes sign when university attendance is added as a potential mediator. However, the birth order effect is smaller overall, and is never significant. We also ran regressions using father's age only: results are similar to those in the main text.

Table 14 reruns the same regressions, dropping fixed effects for respondent's year and month of birth. Table 15 reruns the regressions dropping controls for fluid IQ, height, BMI and self-reported health. In both cases, results are similar to those in the main text.

Tables 16 and 17 rerun our central regressions estimating a separate coefficient for each position in the birth order (with firstborn as the baseline). The basic pattern of our main result is remarkably robust, in both Great Britain and Norway: birth order coefficients are generally negative, and adding mediators always causes them to increase towards zero or to change sign.

We also ran a specification with separate birth order dummies within each family size. Figures 6 and 7 show 95% confidence intervals for the birth order coefficients, from a regression including IQ/height/BMI/health controls but no mediators. Not surprisingly, coefficients are imprecisely estimated. But most birth order coefficients are negative compared to the baseline for firstborns.

Table 18 re-estimates Table 3 using weights from Alten et al. (2022). These weight the UK Biobank sample to match its sampling frame of 40-69 year olds living close to 22 assessment centres. Although these weights probably bring the sample closer to the UK population, the sampling frame

is still not representative of that population: for instance, urban areas are oversampled. Results are similar to those in the main text, although birth order coefficients are absolutely larger in all the specifications.

Table 19 reruns our regressions controlling for several polygenic scores. Results are very close to those in the main text.

Table 20 and 21 rerun our regressions using age of leaving full-time education as a measure of educational SES, instead of the university attendance dummy. Results are similar to those in the main text: controlling for age of leaving full-time education shrinks the effect of birth order substantially.

Table 22 reruns Table 3 excluding families of size 3. Results are very similar to those in the main text.

To examine selection into having a partner (at all), Table 23 regresses being with a partner against own birth order, PSEA and parental age, among individuals with birth order 6 or less in the UK Biobank sample. Birth order has a tiny negative coefficient on being partnered, but this shrinks and becomes insignificant after parental age is included.

Lastly, we run an Oster (2019) style robustness analysis on the effect of education and income on spouse PSEA. This is a formalization of the informal idea that if a coefficient does not change much when a known set of controls is added, it may be robust to other, unobserved controls. The method works by comparing a “short” regression, without alternative controls like BMI and height, to a “medium” regression with those controls. An important input is the maximum R^2 of independent variables on the dependent variable. Here, we use our knowledge about the noise in measured PSEA. We take the ratio of the R^2 of measured PSEA on education to the maximum R^2 of all genetic variables on education, a.k.a. the heritability. We assume that this ratio s gives the proportion of “signal” in measured PSEA, with the rest being noise (from sampling error in the construction of the polygenic score). We then make an assumption about the maximum R^2 of any own variable on spouse’s true PSEA - i.e., about how random the spouse matching process is. We take this to be 50%. Multiplying s by 50% gives the maximum possible R^2 of own variables on spouse’s measured PSEA. The output of the analysis is a value δ^* representing the degree of selection on unobservables relative to observables (with respect to the treatment variable) that would be necessary to eliminate the effect of the independent variable. A δ^* of about 1 is considered a reasonable threshold for robustness, if we assume that measured control variables ought to be at least as important as unmeasured ones.

In UK Biobank, we calculate the maximum R^2 as 0.056.²³ For university attendance, δ^* is 0.941,

²³In other regressions of spouse traits on PSEA, R^2 are indeed below this value (Hugh-Jones et al. 2016; Okbay et al. 2022).

and for income in first job δ^* is 2.03. In MoBa, we calculate the maximum R^2 as 0.131.²⁴ For university attendance, δ^* is 0.99, and for income at age 30, δ^* is 0.275. These results confirm that the results on university attendance are relatively robust, except for results on income in MoBa. Of course, this technique depends crucially on the input assumptions, especially about noise in measured PSEA, the true heritability, and the maximum possible R^2 in spouse matching.

Testing the UK Biobank spouse pair matching

Some of our spouse pairs in UK Biobank could be false positives, i.e. people who are not each others' spouse but simply live in the same postcode. To validate the accuracy of our pairs, we use genetic relationships. Some respondents in the UK Biobank sample have a child (inferred from genetic data) who is also in the sample. Among our spouse pairs, 463 have a genetic child of at least one partner in the sample. For 425 of these, at least one child is the genetic child of both partners. If this subsample is representative, then about 92% of the pairs who have had a child, have had a child together. This is a lower bound estimate, because some of the remaining couples may have had a genetically shared child who is not in the UK Biobank sample. As a point of comparison, 11% of families with dependent children included a stepchild in England and Wales in 2011 (National Statistics 2014).

It is still possible that some pairs in our data may not be actual spouses. These pairs might show a relationship between one partner's phenotype and the other's genotype. For example, maybe early-born children grow up to live in richer postcodes, along with people who have higher PSEA scores (Abdellaoui et al. 2019). This could then bias the results. If the coefficient for "fake pairs" is absolutely larger (smaller) than for real pairs, then our results will be biased away from zero (towards zero).

To sign the bias, we create a dataset of "known fake pairs". These are opposite-sexed pairs who live in the same postcode, but do not share all the characteristics listed for the real pairs. Specifically, from the list of characteristics used to create our real pairs (same homeownership status, same length of time at address, same number of children, attended same assessment center, attended on same day, husband reported living with spouse, wife reported living with spouse) the fake pairs ticked exactly 5 out of 7 boxes.

We again use genetic children to confirm that the fake pairs are "real fakes". Out of 786 genetic children of the fake pairs, only 32 were children of both parents. Thus, the vast majority of fake pairs do not appear to be spouses. Table 24 reruns the regressions of Table 2 using the fake pairs. Although the coefficients on birth order are always negative, and significant when controlling for parent's age, they are always absolutely smaller than the corresponding coefficient in the main text. This suggests that any fake pairs remaining in our data will have the effect of biasing our results towards zero.

Quotations on natural inequality

...your face and figure have nothing of the slave about them, and proclaim you of noble birth.

– *Odyssey*, Odysseus to Laertes

Citizens, we shall say to them in our tale, you are brothers, yet God has framed you differently. Some of you have the power of command, and in the composition of these he has mingled gold, wherefore also they have the greatest honour; others he has made of silver, to be auxiliaries; others again who are to be husbandmen and craftsmen he has composed of brass and iron; and the species will generally be preserved in the children. But as all are of the same original stock, a golden parent will sometimes have a silver son, or a silver parent a golden son.

– Plato *Republic*

Nature would like to distinguish between the bodies of freemen and slaves, making the one strong for servile labor, the other upright, and although useless for such services, useful for political life in the arts both of war and peace. But the opposite often happens – that some have the souls and others have the bodies of freemen.

– Aristotle *Politics*

Sons have no richer endowment than the quality

A noble and brave father gives in their begetting.

– Euripides *Heracleidae*

Abilities come from innate talents, which differ in their capacities and take on different responsibilities in government.

– Liu Shao *Study of human abilities*

His head by nature fram'd to wear a crown,

His hands to wield a sceptre....

– Shakespeare *Henry VI Part 3*

A daughter of a green Grocer, walks the Streets in London dayly with a baskett of Cabbage Sprouts, Dandelions and Spinage on her head. She is observed by the Painters to have a beautiful Face, an elegant figure, a graceful Step and a debonair. They hire her to Sitt. She complies, and is painted by forty Artists, in a Circle around her. The Scientific Sir William Hamilton outbids the Painters, Sends her to Schools for a genteel Education and Marries her. This Lady not only causes the Tryumphs of the Nile of Copenhagen and Trafalgar, but Seperates Naples from France and finally banishes the King and Queen from Sicilly. Such is the Aristocracy of the natural Talent of Beauty.

– John Adams to Thomas Jefferson, on Emma Hamilton
